When oxygen delivery (DO<sub>2</sub>) is reduced below a critical value (DO<sub>2crit</sub>), the tissues oxygen uptake (VO<sub>2</sub>) becomes DO<sub>2</sub> dependent. This reduction in DO<sub>2</sub> below DO<sub>2crit</sub> is associated with the development of tissue hypoxia, as reflected by an increase in blood lactate levels (Lac). Increases in the veno-arterial gradients (VA) for PCO<sub>2</sub> (VAPCO<sub>2</sub>) and pH (VApH) can also be observed in low flow states. The present study tested the hypothesis that the DO<sub>2crit</sub> obtained from repeated measurements of VO<sub>2</sub>, Lac, VAPCO<sub>2</sub> and VApH are in fact similar. We used an anesthetized dog model in which DO<sub>2</sub> is reduced by progressive hemorrhage.

MATERIAL & METHODS

The study included 13 dogs (weight 28.6 ± 2.5 kgs). Anesthesia was induced with thiopental (20 mg.kg<sup>-1</sup>) and maintained with isoflurane (1 MAC = 1.4 % end-tidal). After endotracheal intubation, the dog was mechanically ventilated with air. After splenectomy, DO<sub>2</sub> was reduced by successive withdrawal of 100 ml of blood every 15 min. VO<sub>2</sub> was determined from the expired gas analysis and DO<sub>2</sub> from the product of thermodilution cardiac output (CO) and the arterial O<sub>2</sub> content. Measurements of CO, arterial and mixed venous blood gases, Lac and expired gas concentrations were performed before every blood withdrawal.

In each dog, the DO<sub>2crit</sub> was determined from a dual regression analysis using the least sum of squares technique.

RESULTS

The DO<sub>2crit</sub> obtained from VO<sub>2</sub>, Lac, VAPCO<sub>2</sub> and VApH were 9.2 ± 1.4, 8.8 ± 1.1, 9.0 ± 1.2, and 8.9 ± 1.1 ml.kg<sup>-1</sup>.min<sup>-1</sup>, respectively. The DO<sub>2crit</sub> obtained from VO<sub>2</sub> correlated well with those obtained from Lac (r = .89), VAPCO<sub>2</sub> (r = .81) and VApH (r = .75). The VO<sub>2</sub>, Lac, VAPCO<sub>2</sub> and VApH at DO<sub>2crit</sub> were 5.4 ± 0.9 ml.min<sup>-1</sup>.kg<sup>-1</sup>, 3.1 ± 1.3 mEq/l, -10.9 ± 3.5 mmHg and 0.05 ± 0.02 U, respectively.

CONCLUSIONS

In this hemorrhagic shock model, the onset of tissue hypoxia associated with the profound reduction in DO<sub>2</sub> is reflected by abrupt increases not only in Lac, but also in VAPCO<sub>2</sub> and VApH. Accordingly, these parameters, easily obtained from arterial and mixed venous blood gas sampling, could represent valuable indicators of cellular hypoxia.

TITLE: VENTILATION-PERFUSION INDEX CAN ACCURATELY REFLECT VENOUS ADMIXTURE IN CRITICALLY ILL PATIENTS

INTRODUCTION: The clinical course of the hypoxic state associated with the Adult Respiratory Distress Syndrome (ARDS) can be monitored with serial measurements of venous admixture (Qs/Qt). The determination of Qs/Qt uses simultaneous arterial and mixed venous blood gas measurements and is calculated with the equation, Qs/Qt = (CcO<sub>2</sub> - CaO<sub>2</sub> / CcO<sub>2</sub> - CvO<sub>2</sub>), utilizing oxygen contents of pulmonary capillary, systemic arterial, and mixed venous blood, respectively. The ventilation-perfusion index (VQI = 100 - SaO<sub>2</sub> / 100 - SvO<sub>2</sub>), utilizing oxygen saturations of arterial and mixed venous blood, respectively, has been advocated as a simplified, immediate and less expensive method of monitoring Qs/Qt. Previous clinical comparisons of VQI and Qs/Qt have been made when Qs/Qt has been ≤ 45%. We hypothesized that VQI would also reliably assess Qs/Qt particularly in the range between 45 - 100% as seen in patients critically ill with ARDS.

METHODS: With approval of the institutional Clinical Investigations Committee, 12 adult patients (5 male, aged 25 ± 7 yrs.) were studied and 370 comparisons of calculated Qs/Qt and VQI values made. All patients had severe ARDS; 11 required either extracorporeal membrane oxygenation or experimental use of intravenous oxygenation for respiratory support. Blood gases were sampled as clinically indicated and measurements made utilizing both an IL - 1323 Blood Gas Analyzer and an IL - 282 Hemoximeter. Qs/Qt was calculated by the clinical laboratory computer using the classic equation. Comparisons were made over a wide range of Qs/Qt (8 to 100%), FIO<sub>2</sub> (0.21 - 1.0), PEEP (5 - 30 cm H<sub>2</sub>O), SaO<sub>2</sub> (65 - 99%), SvO<sub>2</sub> (35 - 92%), hemoglobin (6.6 - 14.9 gm%), and PaCO<sub>2</sub> (23 - 74 mmHg). VQI and Qs/Qt correlation was determined by linear regression. A p value < 0.05 was considered significant. Bias and standard deviation of the differences (SDD) were also calculated.

RESULTS: The frequency distribution of calculated Qs/Qt was: <15% (18), 15-30% (81), 30-45% (103), 45-60% (44), 60-75% (33), and >75% (91). Qs/Qt was above 60% in 124 of 370 comparisons. There was a strong correlation (r = 0.973, p < 0.001, slope = 1.072, y intercept = -8.4) over the range of VQI and Qs/Qt values measured. Overall, calculated bias was 4.7 (± 7.6 SDD)%. Maximum bias was 8.7 (± 7.0)% for comparisons in the 30 - 45% Qs/Qt range (figure). Changes in VQI correctly predicted changes in Qs/Qt in 88% of measurements. The incorrectly predicted changes were evenly distributed; 21 false predictions of deterioration and 22 false predictions of improvement.

CONCLUSIONS: In patients with severe ARDS, there was a high correlation between VQI and Qs/Qt over a wide range of Qs/Qt values. Maximal bias was found in the clinically significant 30-45% Qs/Qt range. The direction of Qs/Qt changes was correctly predicted in 88% of comparisons. VQI can provide rapid, relatively inexpensive and, if the correlation extends to saturation measurements utilizing pulse oximetry and fiberoptic SvO<sub>2</sub> monitoring, continuous assessment over a wide Qs/Qt range. Clinical use of VQI should be made with the understanding that variations in correlation and predictability of Qs/Qt changes do occur.

FIGURE The agreement between VQI and Qs/Qt is demonstrated across the range of Qs/Qt measured in patients critically ill with ARDS.
