**ABSTRACT**

The effect of direct-fed microbials (DFM) on fecal shedding of *Escherichia coli* O157:H7 and *Salmonella* in naturally infected feedlot cattle was evaluated in a clinical trial involving 138 feedlot steers. Following standard laboratory methods, fecal samples collected from steers were evaluated for presence of the *E. coli* O157:H7 and *Salmonella* shed in feces after DFM treatment. Sampling of steers was carried out every 3 weeks for 84 days. A significant reduction (32%) in fecal shedding of *E. coli* O157:H7 (*P* < 0.001), but not *Salmonella* (*P* = 0.24), was observed among the treatment steers compared with the control group during finishing. The probability of recovery of *E. coli* O157:H7 from the feces of treated and control steers was 34.0 and 66.0%, respectively. Steers placed on DFM supplement were almost three times less likely to shed *E. coli* O157:H7 (*odds ratio, 0.36; 95% confidence interval, 0.25 to 0.53; *P* < 0.001) in their feces as opposed to their control counterparts. The probability of recovery of *Salmonella* from the feces of the control (14.0%) and the treated (11.3%) steers was similar. However, the DFM significantly reduced probability of new infections with *Salmonella* among DFM-treated cattle compared with controls (nontreated ones). It appears that DFM as applied in our study are capable of significantly reducing fecal shedding of *E. coli* O157:H7 in naturally infected cattle but not *Salmonella*. The factors responsible for the observed difference in the effects of DFM on *E. coli* O157:H7 and *Salmonella* warrants further investigation.

Foodborne illnesses are a substantial health burden in the United States (24). Shiga toxin--producing *Escherichia coli* O157:H7 (STEC O157) and *Salmonella* play a significant role in foodborne infections. In humans, *E. coli* O157:H7 causes acute hemorrhagic colitis with a small percentage resulting in hemolytic uremic syndrome (23), whereas *Salmonella* causes salmonellosis. According to the 2006 FoodNet report (5), the incidence of infections caused by STEC O157 and *Salmonella* did not decrease significantly when compared with baseline data from the period of 1996 to 1999. This indicates that further measures are needed to prevent foodborne illness in order to achieve national health objectives. In 2006, a total of 17,252 laboratory-confirmed cases of infections in FoodNet surveillance areas were identified, of which 6,655 (38.57%) were determined to be associated with *Salmonella* (7). In addition, an estimated 95% of salmonellosis cases involved pathogen transmission mainly by foods of animal origin such as beef (4).

Cattle have been identified as a significant reservoir for *E. coli* O157:H7 (15), and *E. coli* O157:H7-related illness in humans is frequently associated with consumption of undercooked ground beef (3). Contamination of beef carcasses with *E. coli* O157:H7 has been linked to the presence of this organism on hides and in feces of cattle at the time of harvest (1, 9, 10). Also, an association has been reported between *Salmonella* shedding in cattle feces and the prevalence of *Salmonella* on cattle hides and other external surfaces (17). Given that cattle and their products are associated with the majority of cases of *E. coli* O157:H7 and *Salmonella* infections in humans, they represent an attractive target for preharvest intervention as a means of reducing risk to humans (23).

Effective intervention technologies implemented at preharvest to decrease the proportion of cattle carrying *E. coli* O157:H7 and *Salmonella* into slaughter plants may reduce the risk of human exposure to these organisms (29). Numerous preharvest intervention strategies have shown promising results in reducing the prevalence of *E. coli* O157:H7 in cattle including the use of direct-fed microbials (DFM) (2, 3, 8, 22, 28, 30). In addition to reducing the shedding of *E. coli* O157:H7, DFM (*Lactobacillus acidophilus* NP 51) has been reported to exert a dose-response effect on *Salmonella* shedding in cattle (26). The objective of this study was to evaluate the efficacy of feeding DFM *L. acidophilus* (LA 51) and *Propionibacterium freudenreichii* (PF 24) on fecal shedding of *E. coli* O157:H7 and *Salmonella* in naturally infected feedlot cattle.

**MATERIALS AND METHODS**

**Study design.** This was a clinical trial conducted for a period of 84 days from March 2007 through June 2007. One hundred
thirty-eight steers, initially weighing between 220 and 560 kg, were used in the study. The steers were divided into three blocks with the initial mean body weight as the blocking factor. Blocking by weight was aimed at targeting steers that will eventually attain the required weight for slaughter. The three blocks each comprised eight pens (six steers per pen), with an average weight of 446 ± 48.2, 475 ± 44.0, and 494 ± 31.2 kg per steer for blocks 1, 2, and 3, respectively. The allocation of treatments to pens was done randomly. Within each block, two treatments (treatment 1 comprised steers fed DFM, and treatment 2 comprised steers that did not receive DFM [controls]) throughout the finishing period) were assigned randomly to eight blocks, making a total of 12 pens per treatment. In general, one-half of the pens in each block were placed on DFM-supplemented feed, whereas the other half was maintained on DFM-free feed only. All steers were housed at the North Dakota State University (NDSU) cattle feedlot facility located in Fargo, North Dakota.

**Housing and feeding of cattle.** One hundred forty-four 1-year-old steers were received at the NDSU feedlot facility on 26 October 2006. The steers were housed in 24 pens (six steers per pen). Prior to the beginning of the study, 6 of 144 steers died due to various causes, leaving 138 steers in the study. The steers in both groups were initially (October 2006 through February 2007) fed the same the growers’ diet consisting of barley (41.82%), desugared molasses (5.0%), grass hay (15.0%), pressed sugar beet (35.0%), and supplement (3.2%). In the second period (March through June), the steers were switched to high-concentrate finishing diet consisting of barley (82.2%), pressed sugar beet (5.0%), alfalfa-brome hay (5.0%), desugared molasses (5.0%), and mineral supplement (2.9%) with an approximate analysis composition of 7.1% ash, 13.9% crude protein, 21.0% neutral detergent fiber, 8.7% acid detergent fiber, and 40.6% starch on dry matter basis. Both diets were formulated to provide 27.5 mg of calcium, 20.0% protein, 14.0% energy, 7.1% crude ash, 13.9% crude protein, 21.0% neutral detergent fiber, 8.7% acid detergent fiber, and 40.6% starch on dry matter basis. Both diets were formulated to provide 27.5 mg of calcium, 20.0% protein, 14.0% energy, 7.1% crude ash, 13.9% crude protein, 21.0% neutral detergent fiber, 8.7% acid detergent fiber, and 40.6% starch on dry matter basis.

In treatment pens, steers were fed DFM-supplemented finishing diet containing 1 × 10^6 CFU of *L. acidophilus* (LA 51) and 1 × 10^6 CFU of *P. freudenreichii* (PF 34) (Rosell Probiotics, Inc., Montreal, Quebec, Canada) per g of feed daily throughout the finishing period. The DFM were stored under refrigeration and reconstituted daily just before mixing with the feed. Steers in control pens only received the finishing diet through the finishing period. The two groups were monitored for fecal shedding of *E. coli* O157:H7 and *Salmonella*.

**Sampling procedure.** Sampling of cattle was conducted in accordance with the guidelines established by the Institute for Animal Care and Use Committee (IACUC) following a previously described protocol (12). Briefly, each steer was restrained in a hydraulic chute, and about 20 g of feces was collected from the rectum. A new set of sterile polyethylene glove sleeves were used between collection from subsequent steers. The feces were put into sterile plastic cups that were placed on ice before being transported to the laboratory at NDSU for processing. In addition, a sterile dry (cotton) swab was used to swab the dorsal mucosa of the rectal pouch (RAJ). Each RAJ mucosal swab was placed into a 15-ml culture tube containing 3 ml of Trypticase soy broth (Difco, Becton Dickinson, Sparks, Md.) supplemented with ceftime and potassium tellurite (Dynal Biotech ASA, Oslo, Norway). Both the fecal samples and swabs were placed in iced-pack coolers before transport to the laboratory. The sampling procedure was repeated every 3 weeks for the entire finishing period (March to June 2007). The samples were cultured for *E. coli* O157:H7 and *Salmonella*.

**Laboratory methods.** Fecal samples were cultured for *E. coli* O157:H7 as previously described (12). For each sample, a 10-g fecal sample was placed in 90 ml of gram-negative enrichment broth containing ceftime-tellurite (0.05 μg/ml and potassium tellurite (2.5 μg/ml) (Dynal Biotech ASA) and incubated for 6 h at 37°C. One milliliter of this culture was subjected to O157 immunomagnetic separation as described by the manufacturer (Dynal Biotech ASA). Twenty microliters of the bead-bacteria washed mixture was plated on sorbitol-MacConkey agar (Difco, Becton Dickinson) plates containing ceftime (0.05 μg/ml and potassium tellurite (2.5 μg/ml) (CT-SMAC; Dynal Biotech ASA) and incubated overnight at 37°C. Individual sorbitol-nonfermenting colonies were subcultured for isolation on CT-SMAC (Dynal Biotech ASA) plates, and an individual sorbitol-nonfermenting colony from each plate was inoculated onto both MacConkey and Fluorocult agars (Difco, Becton Dickinson). Isolates that fermented lactose but not sorbitol within 24 h and had a negative 4-methylumbelliferyl-β-d-glucuronide (MUG) (Difco, Becton Dickinson) reaction were tested for *E. coli* O157 and H7 antigens by latex agglutination (Remel, Lenexa, Kans.). Similarly, the RAJ mucosal swabs were vortexed for 1 min, followed by a 6-h incubation as described previously (12). One milliliter of this culture was subjected to O157 immunomagnetic separation (Dynal Biotech ASA) as was performed for the fecal samples. A similar cultural and isolation procedure was performed for all the RAJ mucosal swab samples. Positive isolates for O157 antigen by latex agglutination were further tested in two primer-pair multiplex PCR assay that detected genes for Shiga-like toxins 1 (Stx1) (21) and 2 (Stx2) (20). Positive PCR results for *E. coli* O157:H7 indicated a detection of genes for the somatic antigen O157, the flagella antigen H7, and at least one or both Shiga toxins (Stx1 or Stx2).

For *Salmonella*, the samples were cultured in the laboratory using culture methods optimized for the detection of *Salmonella* (14). Briefly, a sterile swab was loaded with fecal sample and preenriched in buffered peptone water (Difco, Becton Dickinson) at 37°C overnight followed by immunomagnetic beads separation specific for *Salmonella* species (Dynabeads anti-*Salmonella*, Dynal Biotech, Inc., Lake Success, N.Y.) according to the manufacturer’s instructions. After the final wash, the beads were transferred to 10 ml of Rappaport Vassiliadis R10 (RV) broth (Becton Dickinson) and incubated (with constant gentle shaking) at 42°C for 24 h. Following incubation, the RV cultures were streaked onto modified brilliant green agar (Becton Dickinson) and mannitol lysine crystal violet brilliant green agar (Oxoid, Basingstoke, UK). Colonies with typical *Salmonella* characteristics (11) were stabbed in 10-ml triple sugar iron agar slants (Becton Dickinson) and the biochemical results read after 24-h incubation as described (11). Presumptive-positive isolates were sent for serotyping to the National Veterinary Services Laboratories (NVSL) (Ames, Iowa).

**Statistical methods.** Epi Info, version 3.3.2 (Centers for Disease Control and Prevention, Atlanta, Ga.), was used for statistical analyses. The prevalence of *E. coli* O157:H7 and *Salmonella* among the treatment and the control groups were compared and statistical significance of the difference assessed at an α set at ≤0.05. The Fisher’s exact test was used to assess the difference where there were <5 values in a cell. The effects of pen, block, and sampling times on the recovery *E. coli* O157:H7 and *Salmonella* were investigated. Least-square means of parameter estimates from the binomial logistic regression was used to estimate adjusted probabilities of fixed effects of treatment, pen, block, and
FIGURE 1. Variation of E. coli O157:H7 and Salmonella shedding in feedlot steers by sampling time.

Results

E. coli O157:H7. The baseline information on the percentage of pretreatment fecal shedding of E. coli O157:H7 in feces among the two selected group of steers were obtained. Treatment (43.9%) and control (44.4%) pens exhibited no statistically significant differences (P = 0.54) (Fig. 1). In total, E. coli O157:H7 was isolated from 194 (42.4%) of 458 fecal samples. Overall, the block had no effect within treatment groups (P = 0.39) on the recovery of E. coli O157:H7 from the steers, whereas pen demonstrated a significant difference in E. coli O157:H7 recovery (P = 0.01). There was no interaction between DFM treatment and sampling time (P = 0.99). However, sampling time significantly influenced E. coli O157:H7 shedding (P = 0.0081). Two steers of 138 were taken out of the study due to illness after the second sampling period. Also, in the second sampling corresponding to the week 3 of DFM treatment, a significant difference (P = 0.001) in the proportion of steers shedding E. coli O157:H7 in treatment groups (16 of 66, 24.2%) and control groups (48 of 71, 67.6%) were calculated (Fig. 1). Similarly, a significant difference (P = 0.003) in the proportions of steers shedding E. coli O157:H7 was recorded at third sampling (week 6), in 29% (n = 18 of 66) treatment and 55.1% (n = 38 of 71) control groups. In the final sampling (week 9 of DFM treatment), only 46 steers were sampled; the rest had been taken for slaughter earlier in the week. Of those sampled, 43.5% (10 of 23) and 13% (n = 3 of 23) of steers in the control and treatment groups, respectively, were positive for E. coli O157:H7. This difference in shedding demonstrated statistically significant differences (P = 0.01). The overall probability of recovery of E. coli O157:H7 from the feces of the treatment and the control steers was 34.0% (66 of 221) and 66.0% (128 of 237), respectively (P < 0.001) (Fig. 1).

Overall, supplementing steers with DFM (L. acidophilus [LA 51] and P. freudenreichii [PF 24]) was associated with a reduction in the natural shedding of E. coli O157:H7 from feces (odds ratio, 0.36; 95% confidence interval, 0.25 to 0.53; P < 0.001).

Salmonella. During the pretreatment sampling, 8.3% (6 of 72) of the fecal samples collected from the steers in the control group and 7.6% (5 of 66) in the group selected for DFM treatment were positive for Salmonella (P = 0.56) (Fig. 2). An increase in the shedding of Salmonella in both groups was recorded during the second sampling (week 3), although no statistical difference (P = 0.355) was recorded in the control (18.1%, 13 of 72) and DFM-treated (12.1%, 8 of 66) groups (Fig. 1). Similar but not statistically different trends (P = 0.17) were observed in the third sampling (week 6) with Salmonella prevalence of 20.3 and 17.7% in the control and treatment steers, respectively (Fig. 1). At the last sampling (week 9), Salmonella was isolated from 3.7% (1 of 27) of steers on DFM supplement, whereas none (0 of 18) was isolated from the control group.

Overall, Salmonella was isolated from 58 of 458 (12.7%) fecal samples tested. All Salmonella belonged to the Typhimurium serotype and the majority (53 of 58, 91%) was Typhimurium Copenhagen. Sampling time was shown to have an effect on the recovery of Salmonella (P = 0.004), whereas block (P = 0.33) and pen (P = 0.79) did not. The overall probability of recovery of Salmonella from the feces of the control (14.0%) and the treated (11.3%) steers were similar (odds ratio, 0.79; 95% confidence interval, 0.46 to 1.37; P = 0.24).

E. coli O157:H7 and Salmonella trends. A comparison of the trends in the shedding status of E. coli O157:
FIGURE 2. Trends in the shedding status of naturally infected steers with E. coli O157:H7 and Salmonella over the feeding periods.

H7 and Salmonella between sampling times in the infected steers is shown in Figure 2. Analysis of the shedding trends of E. coli O157:H7 among the four categories of infected steers (those that maintained shedding, recovered shedders, new shedders, and noninfected steers), showed a significant difference ($P = 0.05$) between DFM-treated (13.8%) and control steers (26.8%) regarding recovered shedders. This trend of a higher recovery rate among untreated steers compared with those fed DFM was seen for both E. coli O157: H7 and Salmonella all the time, although the difference was not always statistically significant. Once infected, DFM did not improve the probability of recovery from both E. coli O157:H7 and Salmonella for those steers that were fed DFM compared with their control counterparts (Fig. 2). For Salmonella, the rate of new shedders (new infection) was significantly higher ($P = 0.023$) in the controls (21.1%) than the treatment group (7.7%) during week 6 (Fig. 2). Also, the rate of new infections for E. coli O157:H7 was observed to be higher among control steers (39.4%) compared with DFM-treated steers (30.8%) during the first 3 weeks, although this difference was not statistically significant. Throughout the study, there was a higher percentage of steers that remained uninfected to both Salmonella and E. coli O157:H7 in the DFM-treated steers compared with controls. This report agrees with the 35% reduction in E. coli O157:H7 prevalence observed in similar studies by Peterson et al. (22), but lower than the 49 to 57% reduction reported by other researchers (2, 28). The differences in results observed are not fully understood; it could possibly be attributed to the difference in strains used in other studies (L. acidophilus [strains NP 45...
and NP 51]). The results of this study suggest that the feeding of L. acidophilus (LA 51) and P. freudenreichii (PF 24) to naturally infected cattle with the numbers of CFUs used in this study will significantly decrease, but not eliminate, natural fecal shedding of E. coli O157:H7.

The shedding of Salmonella in cattle has been reported to be unpredictable and to occur in clusters (27). However, in our study, we observed an increasing trend in Salmonella prevalence from the initial pretreatment prevalence of 8.3 and 7.6% to 20.3 and 17.7% in the control and treatment groups, respectively, although those comparisons were not different between the two treatments. Other researchers have reported either no effect (7) or a decrease (25) in Salmonella prevalence in the feedlot over time. This difference in results could be related to the reported erratic nature of Salmonella shedding in cattle (26) or to lack of effect of DFM used in our study. Also, concentration of cattle in the feedlot may facilitate the fecal-oral transmission of enteric bacteria like Salmonella, which may explain the observed increase in Salmonella shedding in our study.

Interestingly, the DFM treatment of steers did not show a beneficial effect on reduction of Salmonella shedding over the study period. In fact, overall, there was a steady increase in Salmonella shedding over the study period in both controls and treatment cattle. The DFM-treated steers were only 1.3 less likely to shed Salmonella in feces than were untreated counterparts in the control (odds ratio, 0.79; 95% confidence interval, 0.46 to 1.37; P = 0.24). This is an indication that it would not be economically justifiable to use these strains of DFM as applied in this study as a control strategy for reducing Salmonella shedding in feedlot cattle. The incremental increase of Salmonella shedding in both control and treatment groups warrants further investigations into other DFM combinations or alternative strategies for control of Salmonella infection. Contrary to this study, a recent study by Stephens et al. (26), using strains of L. acidophilus NP 51, reported a dose-response–related effect on reduction of Salmonella among steers placed on DFM. Therefore, it is possible that DFM as applied in our study were not at high enough dose to reduce Salmonella shedding among steers.

Interestingly, our study showed that for Salmonella the rate of new shedders (new infection) was significantly higher (P = 0.023) in the controls (21.1%) than the treatment group (7.7%) after 6 weeks on feed. This implies that the DFM were having some protective effect against infection with Salmonella among the steers that were not yet infected. This protective effect against new infections was also observed for E. coli O157:H7 among steers during the first 3 weeks on feed (controls, 39.4%; DFM-treated steers, 30.8%), although the difference was not statistically significant. Also, throughout the study, there was a higher percentage of steers that remained uninfected to both Salmonella and E. coli O157:H7 in the DFM-treated steers than controls, although these differences were not statistically significant. This result may support our hypothesis that, for steers that are not yet infected, DFM may protect them from infection to both Salmonella and E. coli O157:H7. This calls for feeding DFM to steers sooner than later on arrival at the feedlot when fecal shedding of both Salmonella and E. coli O157:H7 are reported to be low (12–14). Previous studies (12–14) have reported E. coli O157:H7 and Salmonella prevalence in steers to be as low as 1.4 and 0.7%, respectively, on arrival at the feedlot. It was evident in our study that more animals were reverting from E. coli O157:H7 shedding to nonshedding status in the control steers (26.8%) than in DFM-fed cattle (13.8%) (P < 0.05) during the sixth week on feed. This implies that, for the steers that are already infected with E. coli O157:H7, treating them with DFM may not improve their recovery rate any better than the nontreated steers. This observation underscores the importance of feeding DFM to steers before they are infected with E. coli O157:H7 for maximum benefit. Notably, this trend of a higher recovery rate among nontreated steers compared with those fed DFM was seen for both E. coli O157:H7 and Salmonella all the time, although the difference was not always statistically significant.

It is possible that the observed difference in effect of DFM on E. coli O157:H7 and Salmonella might be related to the difference in mode of action of the DFM for the two organisms. The mechanism of action by which DFM decrease the prevalence of E. coli O157:H7 and other enteric pathogens have been attributed to various phenomena, such as competitive interactions, production of volatile fatty acids, enhancement of specific and total IgA secretion, and secretion of specific antibodies against Stx1, Stx2, and Stx2-producing E. coli cells among other effects (19). In a recent study in vitro, the mode of action of L. acidophilus LA-5 was shown to be through secretion of molecule(s) that either act as quorum sensing signal inhibitors or directly interact with bacterial transcriptional regulators controlling the transcription of EHEC O157 proteins involved in the colonization of the intestinal tract by EHEC O157:H7 (18). Other normal bacterial flora, some of which are of bovine origin (such as Bacillus circulans), have been reported to inhibit Salmonella enterica serovars Typhimurium DT 104 in vitro (6). Further investigations into more promising alternative strategies for control of Salmonella infection in cattle are warranted. Also, the mechanism for the observed difference in effect of DFM on E. coli O157:H7 and Salmonella warrants further investigation.

The present study provides evidence that DFM as applied in our study were capable of significantly reducing fecal shedding of E. coli O157:H7 in naturally infected cattle but not Salmonella. However, once infected, DFM did not improve the probability of recovery from E. coli O157:H7. Additionally, DFM significantly reduced probability of new infections with Salmonella among DFM-treated cattle compared with controls.
