Nutritional rickets among children in the United States: review of cases reported between 1986 and 2003

Pamela Weisberg, Kelley S Scanlon, Ruowei Li, and Mary E Cogswell

ABSTRACT

Reports of hypovitaminosis D among adults in the United States have drawn attention to the vitamin D status of children. National data on hypovitaminosis D among children are not yet available. Reports from 2000 and 2001 of rickets among children living in North Carolina, Texas, Georgia, and the mid-Atlantic region, however, confirmed the presence of vitamin D deficiency among some US children and prompted new clinical guidelines to prevent its occurrence. We reviewed reports of nutritional rickets among US children < 18 y of age that were published between 1986 and 2003. We identified 166 cases of rickets in 22 published studies. Patients were 4-54 mo of age, although in 17 studies the maximal age was < 30 mo. Approximately 83% of children with rickets were described as African American or black, and 96% were breast-fed. Among children who were breast-fed, only 5% of records indicated vitamin D supplementation during breast-feeding. The American Academy of Pediatrics (AAP) recently recommended a minimal intake of 200 IU/d vitamin D for all infants, beginning in the first 2 mo of life. AAP recommends a vitamin D supplement for breast-fed infants who do not consume at least 500 mL of a vitamin D-fortified beverage. Given our finding of a disproportionate number of rickets cases among young, breast-fed, black children, we recommend that education regarding AAP guidelines emphasize the higher risk of rickets among these children. Education should also emphasize the importance of weaning children to a diet adequate in both vitamin D and calcium. Am J Clin Nutr 2004;80(suppl):1697S–705S.

KEY WORDS Vitamin D deficiency, rickets, breast-feeding, case reports, children, African American children

INTRODUCTION

Recent studies reported high rates of hypovitaminosis D among adolescents and adults in the United States, particularly among black subjects (1-3). National data on the prevalence of hypovitaminosis D among children are not yet available; however, published reports from 2000 and 2001 of cases of clinical nutritional rickets among young children living in North Carolina (4), Texas (5), Georgia (6–8), and the mid-Atlantic region (9) confirmed the presence of severe vitamin D deficiency among some US children and stimulated renewed interest in the disease. Reports from 2000 and 2001 of cases of rickets among children living in North Carolina, Texas, Georgia, and the mid-Atlantic region, however, confirmed the presence of vitamin D deficiency among some US children and prompted new clinical guidelines to prevent its occurrence. We reviewed reports of nutritional rickets among US children < 18 y of age that were published between 1986 and 2003. We identified 166 cases of rickets in 22 published studies. Patients were 4-54 mo of age, although in 17 studies the maximal age was < 30 mo. Approximately 83% of children with rickets were described as African American or black, and 96% were breast-fed. Among children who were breast-fed, only 5% of records indicated vitamin D supplementation during breast-feeding. The American Academy of Pediatrics (AAP) recently recommended a minimal intake of 200 IU/d vitamin D for all infants, beginning in the first 2 mo of life. AAP recommends a vitamin D supplement for breast-fed infants who do not consume at least 500 mL of a vitamin D-fortified beverage. Given our finding of a disproportionate number of rickets cases among young, breast-fed, black children, we recommend that education regarding AAP guidelines emphasize the higher risk of rickets among these children. Education should also emphasize the importance of weaning children to a diet adequate in both vitamin D and calcium.

Rickets is associated with biochemical abnormalities, bone deformities, impaired growth, developmental delays, and, late in the course of the disease, seizures. Vitamin D₃ functions with parathyroid hormone (PTH) to maintain intracellular and extracellular calcium concentrations within a physiologically acceptable range (11). When vitamin D concentrations are inadequate, intestinal absorption of calcium is decreased. The slight decrease in serum calcium concentrations that results stimulates PTH secretion, which in turn mobilizes calcium and phosphorus from bone to restore serum calcium concentrations to normal levels. Serum alkaline phosphatase (ALP) concentrations increase once clinical signs of rickets are apparent. Low serum 25-hydroxyvitamin D [25(OH)D] concentrations can confirm vitamin D deficiency as the cause of rickets if treatment with vitamin D has not yet been initiated, whereas serum 1,25-dihydroxyvitamin D concentrations can be low, normal, or elevated in vitamin D deficiency (11). The biochemical abnormalities detected vary, depending on the stage of deficiency and the PTH response in mobilizing calcium and phosphorus. The characteristic bone changes of rickets include bowing of the legs, rachitic rosary of the rib cage, frontal bossing, and epiphyseal enlargement of the wrists and ankles.

Vitamin D is available to humans through the photochemical action of sunlight or ultraviolet light on 7-dehydrocholesterol in skin and through dietary sources such as fish liver oils, fatty fish, and foods fortified with vitamin D, particularly liquid cow’s milk, infant formula, and breakfast cereals (11, 12). Infants with darkly pigmented skin are at elevated risk for deficiency because melanin in the skin competes with 7-dehydrocholesterol for ultraviolet-B photons, thus decreasing vitamin D₃ synthesis in the skin (12, 13).

In 1985, Cosgrove and Dietrich (14) reviewed 65 clinical cases of nutritional rickets that were reported between 1975 and 1985, in 11 publications, from medical centers in 9 US states. The children with rickets were 2-45 mo of age and were still breast-feeding or were consuming a milk-free vegetarian diet at the time of diagnosis. Among the 44 children for whom race was reported, 40 were described as black. The purpose of our study was to review all cases of nutritional rickets reported in the literature between 1986 and 2003 and to provide an expanded review of...
characteristics common to its occurrence. Information on common factors associated with rickets in the United States should help health care providers educate families regarding the new AAP clinical guidelines on preventing rickets and vitamin D deficiency, by emphasizing the children who are at greatest risk of deficiency.

METHODS

This review includes published case reports of nutritional rickets among children in the United States. The MEDLINE database was used to identify all case reports of rickets published between 1986 and 2003. Key words used in the MEDLINE search were rickets and vitamin D deficiency. The search was limited to reports of children < 18 y of age, in the United States. Eighteen articles met our selection criteria. Another 6 articles were identified from the references of the articles, for a total of 24 articles published between 1986 and 2003. The 24 publications reported on 22 case studies; 3 articles (6–8) reported on different cases. We reviewed all reports to examine the region, month, and year of diagnosis, clinical findings, age, sex, race/ethnicity, infant feeding and supplementation practices, and exposure to sunlight. Abnormal clinical findings were designated by the medical laboratory or clinic making the assessment and were limited to those reported in the article. Reference ranges for the laboratory assays used varied among the studies, but there was insufficient information for individual cases to set standard cutoff values for this review. Furthermore, not all studies provided information on the biochemical assays performed.

RESULTS

Characteristics of the clinical rickets cases reported in the literature between 1986 and 2003 are presented in Table 1. The cases were ascertained through case findings and clinical encounters in at least 17 states and at 1 center representing the mid-Atlantic region (4–9, 15–32). The 17 states that reported cases represented all regions of the United States. A total of 166 cases of rickets were reported in the 22 case reports. Patients presented to the hospital or clinic with clinical signs such as delayed growth or motor development, inability to walk, bone abnormalities, or seizures and were diagnosed on the basis of radiographic, biochemical, or clinical evidence of rickets. Of the 159 cases with radiographs (one study had no radiographs for 7 cases) (18), all except 3 showed radiographic evidence of rickets, including metaphyseal flaring, cupping, or fraying. Of the 3 cases with no radiographic evidence, one involved an 8-mo-old child with normal radiographic findings but biochemical evidence of hypovitaminosis D, hypocalemia, hyperparathyroidism, and elevated ALP concentrations who responded to vitamin D and calcium supplementation (23), one involved a 4-mo-old child with normal radiographic findings but biochemical evidence of hypocalemia and elevated ALP concentrations who responded to vitamin D and who was described as a child with “biochemical rickets” by the authors (27), and one involved a 7-mo-old child with normal scout films of the abdomen and chest who presented with a hypocalemic seizure, elevated ALP and PTH concentrations, and low serum 25(OH)D concentrations and who responded clinically to combined vitamin D and calcium supplementation (26).

Biochemical indicators reported in the studies included low serum 25(OH)D concentrations for 68% of the children tested (67 of 98 children), hypocalemia for 55% of those tested (77 of 141 children), hypophosphatemia for 64% of those tested (95 of 148 children), elevated ALP concentrations for 99% of those tested (142 of 144 children), and hyperparathyroidism for 94% of those tested (74 of 79 children). Biochemical studies were sometimes performed after treatment with vitamin D had been initiated, as was the case for the 4 children with normal serum 25(OH)D concentrations in the North Carolina study (4). Clinical findings included seizures, failure to thrive, delay or regression in motor development, weight-for-age or length-for-age less than the 5th percentile, and bone abnormalities, such as bowing of the legs, fractures, rachitic rosary, frontal bossing, or widened wrists and ankles.

The children with rickets described in the 22 case studies ranged from 4 to 54 mo in age at the time of diagnosis (Table 1). In 17 studies, however, the maximal age at diagnosis was < 30 mo. Only 3 studies presented cases involving children < 6 mo of age (4, 27, 32). When mean ages were reported (15 studies), they ranged from 10.5 to 25 mo. Among the 12 studies that reported the length of gestation for all cases (5, 6, 9, 17, 19, 21–24, 30–32), all except 2 cases were described as full term (37 wk of gestation completed). The 2 preterm cases were 35-wk gestations (data not shown) (32).

Most studies provided the sex and racial/ethnic distribution of cases, indicating that overall 54% of cases (80 of 148 cases) with reported sex were male and 83% (138 of 166 cases) were African American or black, 4% nonwhite (of African American or Indian descent), 6% white, 2% Hispanic, 2% Alaskan native, and ≤ 1% Middle Eastern, Asian, or unknown. The 5 studies that reported cases among white children were reports from northern states, ie, Washington, Minnesota, New York, Connecticut, and New Hampshire (18, 23, 27, 30, 32).

A common characteristic among cases was that the dietary history indicated that the children were breast-fed without vitamin D supplementation. All except 7 cases (96%, 152 of 159 cases) for which this information was reported involved children who were breast-fed. Among the 151 children who were breast-fed and for whom it was reported whether supplementation was used, only 8 (5%) received a vitamin D supplement during the breast-feeding period, as indicated in the medical records or by the parent (18, 25, 27, 32). Administration of the supplement was reported as sporadic or intermittent for 2 of those children. Among the studies that reported on liquids introduced after weaning (6, 15, 17, 18, 25, 30), consumption of vitamin D-fortified milk was reported by the parents for only 3 children (15, 18, 25) and a vitamin D-enriched soy beverage was reported by the parent of 1 child (30). The authors of 5 studies made qualitative comments about poor overall dairy consumption among the patients (5, 17, 24, 27, 32). Kreiter et al (4) reported poor intake of fortified cow’s milk and other dairy foods among patients ≥ 1 y of age.

Twelve studies provided information on sunlight exposure, but they varied greatly in how they reported exposure (5, 6, 16, 17, 19–22, 24, 27, 29, 31). Parents interviewed by Tomashek et al (6) responded that sun exposure was minimal for 3 of 6 children with rickets. The mother of one child with rickets provided by Bhowmick et al (19) reported that she restricted sunlight exposure for the first 8 mo of her infant’s life, and the mother of
the child presented by Hayward et al (16) reported that she remained indoors with her child most of the time. In 7 other studies, the authors provided qualitative reports that some of the children with rickets were not outside very often (20, 21, 27, 29, 31) or had “limited sunlight exposure” (16, 17). Shah et al (5) reported that there was no evidence of reduced sunlight exposure for the 9 children with rickets in their study.

All except 3 studies (6, 22, 32) reported on the responses of all cases to treatment (data not shown). Those studies reported resolution of the radiographic and biochemical features of all rickets cases with vitamin D treatment. The vitamin D was administered with or without the addition of a calcium supplement or dairy foods. DeLucia et al (32) reported on responses to treatment for 3 of the 43 cases presented and found that 1 case responded to calcium supplementation without vitamin D.

**DISCUSSION**

In a 1985 review, Cosgrove and Dietrich (14) described characteristics of 65 cases of nutritional rickets reported in the literature between 1975 and 1985. The cases described involved children 2-45 mo of age who had been breast-fed and either were breast-feeding or had been breast-fed and either were not breast-feeding or had weaned. The cases described involved children 2-45 mo of age who had been breast-fed and either were breast-feeding or had been breast-fed and either were not breast-feeding or had weaned.

The authors of the study reported that the cases were divided into 3 groups: those who were breast-fed, those who were not breast-fed, and those who were weaned. The cases were divided into 3 groups: those who were breast-fed, those who were not breast-fed, and those who were weaned.

Notably, the study did not include children who were on vitamin D supplementation or calcium supplementation without vitamin D. The study did not include children who were on vitamin D supplementation or calcium supplementation without vitamin D.

The study described 3 cases: one in which the child was breast-fed, one in which the child was weaned, and one in which the child was not breast-fed. The study described 3 cases: one in which the child was breast-fed, one in which the child was weaned, and one in which the child was not breast-fed.

vitamin D and calcium. All except 3 cases showed radiographic

evidence of rickets. In the 19 studies with information on re-

still breast-feeding or were consuming a milk-free vegetarian
diet at the time of diagnosis. Among the 44 children for whom race was reported, 91% were described as black. We found sim-
lar characteristics among the 166 clinical cases of rickets pub-
lished in the literature between 1986 and 2003, and we expanded our review to include information on vitamin D supplementation
and details of clinical presentation and responses to treatment. The clinical cases we reviewed occurred among children 4-54 mo
of age; 83% were described as black, and 96% were breast-fed. Among breast-fed infants, only 5% of records indicated that the infant received supplementation with vitamin D during breast-
feeding. When additional dietary information was available, we
noted that often these children were weaned onto a diet low in
vitamin D and calcium. All except 3 cases showed radiographic
evidence of rickets. In the 19 studies with information on re-
sponses to treatment, all rickets cases treated with vitamin D responded clinically and biochemically to treatment. The vita-
min D was administered with or without added calcium or dairy
foods. One case responded to calcium without vitamin D (32).

Specker et al (35) estimated that white infants require ~30 min of sunlight per week to obtain adequate vitamin D if they are
wearing only a diaper and they require 2 h per week if they are
fully clothed with no hat. However, because melanin in skin
decreases the amount of vitamin D3 synthesized from sunlight,
infants with dark skin need to spend more time exposed to sun-
light to synthesize the same amounts of vitamin D3 as infants with
light skin. One study suggested that an adult with dark skin would
need to spend at least 6 times as long a time exposed to sun-
light to synthesize the same amount of vitamin D as an adult with white
skin (36). Comparable figures are not available for infants. Fur-
thermore, infants living at northern latitudes in the US synthesize
less vitamin D3 from sunlight because more ultraviolet-B pho-
tons are absorbed by the atmosphere (5, 11). In our review, we
noted that all rickets cases involving white infants occurred
among infants living at northern latitudes. Finally, breast-fed
infants may not obtain adequate vitamin D3 from sunlight be-
cause exposure is limited, because of parental concerns about air
quality or subsequent skin cancer risk. In fact, the AAP re-
commends that infants < 6 mo of age be kept out of direct sunlight to
reduce the risk of skin cancer (37).

Recommendations for vitamin D supplementation for infants
have varied somewhat since 1963, when the AAP recommended
that all infants receive supplementation with vitamin D (38). The
recommendation was modified in 1978, when vitamin D was
listed as a possible supplement for breast-fed infants (39). In
1997, the AAP Work Group on Breastfeeding (40) recom-
manded that all infants be breast-fed for a minimum of 12 mo and
noted that vitamin D might need to be given before 6 mo of age
to infants whose mothers have vitamin D deficiencies and those
with inadequate exposure to sunlight. Near the same time, the

2 Winter was defined as December through February; spring as March through May; summer as June through August, and fall as September through November.

3 Clinical findings of low or abnormal were defined by the medical laboratory or clinic that performed the assessment; therefore, thresholds varied among studies.

4 Cases defined by biochemical evidence of rickets, (low serum calcium, low serum phosphorus, high alkaline phosphatase, and high serum PTH concentrations).

5 Cases defined by radiographic evidence of rickets, (metaphyseal flaring, cupping, fraying, and osteopenia).
In April 2003, as a result of continued reports of rickets in the United States and inconsistent recommendations regarding who should receive supplementation with vitamin D, the AAP published new guidelines on preventing rickets and vitamin D deficiency among children (10). The AAP (10) recommended that, "all infants, including those who are exclusively breastfed, have a minimum intake of 200 IU of vitamin D per day beginning during the first 2 months of life" (p. 908). Because the adequate intake of 200 IU/d cannot be met with human milk alone and the adequacy of sunlight exposure is difficult to determine for all breast-fed infants, the AAP recommended that all breast-fed infants be given supplemental vitamin D by 2 mo of age unless they are consuming at least 500 mL of vitamin D-fortified formula or milk (10). In addition, non-breast-fed infants who consume < 500 mL of vitamin D-fortified formula or milk should be given a vitamin D supplement. The AAP recognizes that variations in this guideline may be appropriate in specific circumstances (10). Evaluation of physician advice regarding vitamin D supplementation for infants since the release of the new guidelines will be important, as will continued surveillance of hypovitaminosis D and rickets cases in the United States.

Currently, there is no national surveillance of diagnosed clinical cases of nutritional rickets in the United States. The National Hospital Discharge Survey (NHDS) data can be used to provide national estimates of hospitalizations for diagnosed conditions, including rickets (42). Scanlon and Grummer-Strawn (unpublished data cited in reference 43) used the NHDS data to estimate that 9 children per 1 million children in the population were hospitalized with rickets between 1990 and 1998. However, they concluded that the rarity of rickets diagnoses in the NHDS (ie, 20 cases in 9 y) results in an unstable estimate of rickets that should be interpreted with caution (43). Furthermore, rickets cases resulting from nutritional deficiency cannot be distinguished from rickets cases resulting from other causes in the NHDS. Only one of the case groups we reviewed provided an estimate of the incidence of nutritional rickets in the population (7). In that study, the rate of 5 cases per 1 million children 6 mo to 5 y of age reflects hospitalized cases of nutritional rickets in one US state during a 2.5-y period (7).

Breast-feeding is the preferred method of infant feeding and provides infants with important nutrients and immunologic factors (44, 45). Breast milk alone, however, does not provide infants with adequate vitamin D (10). Most breast-fed infants do not develop clinical vitamin D deficiency because sufficient vitamin D is synthesized through casual sunlight exposure or obtained from a supplement. As noted above, however, environmental conditions and concerns, as well as skin pigmentation and covering, make it difficult to rely on sunlight as a source of vitamin D for exclusively breast-fed infants. Our review identified breast-feeding without vitamin D supplementation among black children as a key similarity among cases. The biologic mechanisms relating these factors to vitamin D deficiency are well established. The new AAP clinical guideline to provide a minimal intake of 200 IU/d vitamin D for all infants, beginning in the first 2 mo of life, should be emphasized in the education of all families but particularly the families of children at greatest risk of vitamin D deficiency. Furthermore, children should be weaned to a diet adequate in both vitamin D and calcium.
