## Abstract

Cancer cells can resist the effects of DNA-damaging therapeutic agents via utilization of DNA repair pathways, suggesting that DNA repair capacity (DRC) measurements in cancer cells could be used to identify patients most likely to respond to treatment. However, the limitations of available technologies have so far precluded adoption of this approach in the clinic. We recently developed fluorescence-based multiplexed host cell reactivation (FM-HCR) assays to measure DRC in multiple pathways. Here we apply a mathematical model that uses DRC in multiple pathways to predict cellular resistance to killing by DNA-damaging agents. This model, developed using FM-HCR and drug sensitivity measurements in 24 human lymphoblastoid cell lines, was applied to a panel of 12 patient-derived xenograft (PDX) models

of glioblastoma to predict glioblastoma response to treatment with the chemotherapeutic DNA-damaging agent temozolomide. This work showed that, in addition to changes in *O*<sup>6</sup>-methylguanine DNA methyltransferase (MGMT) activity, small changes in mismatch repair (MMR), nucleotide excision repair (NER), and homologous recombination (HR) capacity contributed to acquired temozolomide resistance in PDX models and led to reduced relative survival prolongation following temozolomide treatment of orthotopic mouse models *in vivo*. Our data indicate that measuring the combined status of MMR, HR, NER, and MGMT provided a more robust prediction of temozolomide resistance than assessments of MGMT activity alone. *Cancer Res*; 77(1); 198–206. ©2016 AACR.

## Introduction

Therapy resistance is a universal problem in cancer treatment, and our understanding of its origins remains incomplete. Many cancers can initially be treated effectively with chemotherapy and radiation. However, some cancers are innately resistant to therapy, and most cancers acquire resistance to therapy over the course of treatment. Consequently, patients who do not benefit from treatment are needlessly subjected to the severe and sometimes lasting side effects of chemotherapy and radiotherapy, including an increased risk of second primary cancers. Moreover, precious time is lost, during which alternative and potentially more effective therapy could have been applied.

Most cancer therapy regimens include chemotherapy and radiotherapy, both of which damage DNA, killing cancer cells by inducing damage that interferes with DNA replication and transcription, ultimately activating cell death pathways. Efficient repair of DNA damage can render cells resistant to killing. Each drug may induce several different types of DNA damage, and at

least 6 major DNA repair pathways, as well as numerous sub-pathways, are involved in the repair of damage (1–3). Accordingly, the DNA repair pathways involved in acquired resistance mechanisms vary from drug to drug, and all of the major DNA repair pathways can alter the sensitivity of cancer cells to DNA damaging agents.

Glioblastoma is an aggressive cancer with a median survival of 12 to 15 months under the standard of care treatment of aggressive surgery, radiation, and chemotherapy. Almost all patients succumb to this disease, reflecting intrinsic or acquired resistance to frontline treatment with radiotherapy combined with the alkylating agent temozolomide (4). Temozolomide is one of several chemotherapeutic S<sub>N</sub>1-type methylating agents, including dacarbazine and procarbazine, which induce a similar spectrum of methylated DNA bases, among which *O*<sup>6</sup>-methylguanine (*O*<sup>6</sup>-MeG) is the predominant cytotoxic DNA lesion (5). Promoter hypermethylation of the *MGMT* gene, encoding a protein that repairs *O*<sup>6</sup>-MeG, has been used to identify patients whose tumors are *O*<sup>6</sup>-methylguanine DNA methyltransferase (MGMT)-deficient and are thus more likely to benefit from temozolomide therapy (6). However, multiple DNA repair pathways affect the sensitivity of cells to killing with S<sub>N</sub>1-type methylating agents (1), suggesting that successful personalized therapy based on DRC in glioblastoma will require multiplexed measurements of repair activity. Progress toward this goal has been significantly hindered by a lack of quantitative, high-throughput assays for multiple DNA repair pathways, and the challenges of predicting phenotypes from genetic or other omics approaches (7).

Here we apply recently developed fluorescence-based multiplexed host cell reactivation (FM-HCR) assays to measure DNA repair capacity (DRC) for multiple repair pathways in a set of human cell lines (8). We present mathematical models that

predict sensitivity to DNA damaging agents from DRC data. We then apply FM-HCR assays to assess global DRC in patient-derived xenograft (PDX) models of glioblastoma. Our mathematical model predicts the effectiveness of temozolomide therapy both for killing glioblastoma cells *in vitro* and for prolonging the survival of glioblastoma tumor-bearing mice upon temozolomide treatment *in vivo*. The model integrates DRC across four repair pathways, and outperforms predictions made based on tumor MGMT activity alone. This work lays the foundation for using functional assays to make quantitative, personalized predictions concerning the effectiveness of cancer therapy.

## Materials and Methods

### PDX models and cell culture

Lymphoblastoid cells, from the Coriell Cell Repository, were maintained in log phase in RPMI media supplemented with 15% FBS plus penicillin and streptomycin (8). Cells were obtained in 2001. The Coriell Cell Repository authenticates and tests cell cultures for contamination with mycoplasma, bacteria, and fungi; cells have not been authenticated by the authors. For cell cultures derived from glioblastoma PDX lines, flank glioblastoma tumor xenografts were excised, dissociated into single-cell suspensions, and cultured in DMEM with 10% FBS as previously described (9).

### MMS and temozolomide sensitivity assays

Lymphoblastoid cell lines were assayed for sensitivity to BCNU (reported previously in ref. 10) and temozolomide using a cell proliferation assay that measures quenching of DNA-bound Hoechst 33258 fluorescence by BrdUrd incorporated during DNA synthesis (10, 11). Cells were suspended in 300  $\mu$ L serum free media at  $4.5 \times 10^5$  cells/mL, and treated at a final concentration 240  $\mu$ mol/L temozolomide for 1 hour at 37°C. Cells were centrifuged for 5 minutes at 450 g, and washed once with 200  $\mu$ L PBS. Next, cells were suspended in 280  $\mu$ L complete media, and subsequently cultured in flat bottom 96-well plates. After two doubling times, BrdUrd was added to achieve a final concentration of 45  $\mu$ mol/L. After two additional doubling times, cells were stained with Hoechst 33258 and analyzed as previously reported (10). Sensitivity to MNNG and sensitivity to MMS were measured using a previously described cell proliferation assay (12). Briefly, logarithmically growing cells were treated with 0.4 mmol/L MMS or left untreated. After

72 hours, % control growth was calculated from the ratio of the total number of viable-treated cells divided by the total number of viable untreated cells using a Vi-CELL cell viability analyzer with trypan blue staining to exclude dead cells.

### FM-HCR assays

FM-HCR assays in lymphoblastoid cell lines were carried out as previously described (8). For FM-HCR assays in PDX lines, glioblastoma cells were seeded at 50,000 cells per well in a 24-well tissue culture plate 24 hours before transfection. 0.5  $\mu$ g of plasmid mixtures composed of previously described reporter plasmids for the MGMT, mismatch repair (MMR), nucleotide excision repair (NER), non-homologous end joining (NHEJ), and homologous recombination (HR) pathways were transfected into cells using "Lipofectamine 2000 LTX with plus reagent" (Thermo Fisher). At 24 hours posttransfection, cells were analyzed for fluorescent reporters by flow cytometry and DRC for both lymphoblastoid cells and glioblastoma cells was calculated in terms of % reporter expression as previously described (8).

### Mathematical modeling

The overall modeling approach is summarized in Supplementary Fig. S1. Following log-transformation of FM-HCR data, Z-scores for relative DRC among the 24 lymphoblastoid cell lines were generated for each pathway using Eq. 1:

$$Z_{ij} = \frac{x_{ij} - \bar{x}_{ij}}{\sigma_j}, \quad (1)$$

where  $Z_{ij}$  is the Z-score for a DNA repair pathway in cell line  $i$  in pathway  $j$ ,  $x_{ij}$  is the DRC for a given pathway  $j$  in cell line  $i$ ,  $\bar{x}_{ij}$  is the mean value of the DRC in pathway  $j$  over the 24 lymphoblastoid cell lines ( $i = 1-24$ ), and  $\sigma_j$  is the standard deviation of the DRC in pathway  $j$ . Z-scores were also generated for relative DRC among the 12 PDX models of glioblastoma using the same approach. Because there is an inverse relationship between % reporter expression and DRC for the MGMT reporter (larger signal represents lower activity), Z-scored MGMT data were multiplied by  $-1$ . Simple linear regression was used to generate the models #1 and #4, denoted as "MGMT" in Table 1. These models relate MGMT activity to sensitivity to killing with temozolomide and MNNG. A graphical interpretation of the parameters associated with model #1 can be generalized to the multiple linear models, and is detailed in Supplementary

**Table 1.** Linear models relating sensitivity to DNA-damaging agents to DNA repair capacity in multiple pathways

Agent	#	Model	Equation	$R^2_{FIT}$	$R^2_{LOO}$	AUC
MNNG	1	MGMT	$13.3 * MGMT + 59$	0.41	0.33	0.54
	2	MLR	$13.8 * MGMT - 9.3 * MMR + 6.8 * HR + 4.4 * NER - 2.3 * NHEJ + 59$	0.68	0.49	0.89
	3	MLR <sub>L</sub>	$13.3 * MGMT + 8.1 * HR - 7.0 * MMR + 59$	0.63	0.50	0.74
TMZ	4	MGMT	$19.0 * MGMT + 71$	0.61	0.50	0.54
	5	MLR	$17.5 * MGMT + 8.5 * NER + 8.3 * HR - 3.6 * MMR - 0.2 * NHEJ + 71$	0.90	0.81	0.86
	6	MLR <sub>L</sub>	$17.4 * MGMT + 8.5 * NER + 8.2 * HR - 3.5 * MMR + 71$	0.90	0.84	0.86
BCNU	7	MLR	$10.4 * MGMT + 2.5 * NER + 2.2 * NHEJ - 1.3 * MMR + 0.3 * HR + 33$	0.54	0.19	0.80
	8	MLR <sub>L</sub>	$10.6 * MGMT + 33$	0.49	0.40	0.54
MMS	9	MLR	$6.9 * HR + 5.8 * NHEJ + 5.6 * NER + 5.2 * MGMT - 1.5 * MMR + 44$	0.38	0.06	0.71
	10	MLR <sub>L</sub>	$8.9 * HR + 44$	0.17	0.07	0.71

NOTE: The models are numbered under column heading "#".  $R^2_{FIT}$  is the goodness of fit for each model;  $R^2_{FIT}$  can adopt values between 0 (no fit at all) and 1 (perfect fit).  $R^2_{LOO}$  is a measure of the predictive accuracy for each model and is calculated from exhaustive leave-one-out cross-validation presented graphically in Supplementary Fig. S2. Once again,  $R^2_{LOO}$  can adopt values between 0 (no fit at all) and 1 (perfect fit). AUC is a statistic that measures the performance of the models when they are used to classify the PDX models as sensitive versus resistant. AUC can adopt values between 0 (all samples are classified incorrectly) and 1 (all samples are classified correctly). AUC is calculated from ROC curves (Fig. 5) generated using the sensitivity of PDX models calculated from the respective models and the actual status of each glioblastoma model (sensitive or resistant)

Fig. S2. MATLAB scripts (provided in the Supplementary Information) were run to generate linear models using DRC in five pathways in the lymphoblastoid cell lines as the predictor variables and sensitivity to cell killing (measured as % control growth) with the DNA damaging agents temozolomide, MNNG, MMS, or BCNU as the response variable. First, multiple linear regression (MLR) models were fit to all five DNA repair pathways; these models are listed as "MLR" models in Table 1. Then, LASSO regression was performed to select optimal combinations of DRC predictor variables for incorporation into MLR models of sensitivity to cell killing with each DNA damaging agent (13). LASSO regression was carried out in MATLAB to return least squares regression coefficients for a set of 100 values of the regularization coefficient  $\lambda$ , which determines the size of the penalty for coefficients remaining in the model. The value of  $\lambda$  is gradually increased until the least squares regression coefficients for all five predictor variables take a value of zero, resulting in a family of combinations of predictor variables. MLR was performed and evaluated with exhaustive leave-one-out cross validation using the combination of predictor variables selected by LASSO at each value of  $\lambda$ ; those for which LASSO returned least squares regression coefficients equal to zero were excluded from MLR analysis.  $R^2$  parameters were calculated for the relationship between predicted sensitivities obtained from cross-validation versus the known sensitivity for each cell line, and the model yielding the largest  $R^2$  values were selected. Plots of sensitivity predicted from leave-one-out cross-validation versus observed sensitivity are presented in Supplementary Fig. S3. MLR models using the combination of predictor variables selected using LASSO are listed as "MLR<sub>L</sub>" in Table 1.

Receiver operating characteristic (ROC) analysis was carried out in MATLAB using PDX sensitivities calculated from mathematical models and the actual sensitivity status. DRC data were input into the models in Table 1 to calculate the predicted sensitivity for each PDX model. To evaluate the performance of the models, ROC curves were generated, and the area under the curve (AUC) computed (Table 1). ROC analysis provides a quantitative estimate and graphical representation of the accuracy of predictive assays (14), and is particularly useful when the test result, reported on a continuous scale, is to be used to predict a binary variable, as in the present case. The ROC curve shows the relationship between the true positive rate and the false-positive rate as the discrimination threshold is varied. For an ideal assay,  $AUC = 1.0$ , indicating that the discrimination threshold can be set in such a way that all true positives can be correctly called without calling any false positives; the distributions of values given by the assay for the positive and negative populations are completely separated. By contrast, for an assay that only performs as well as random chance, the distributions are indistinguishable, and  $AUC = 0.5$ , because there are equal chances of calling a positive or a negative at all discrimination thresholds. The true positive rate is equivalent to assay sensitivity, and the false positive rate is calculated from  $1 - (\text{assay specificity})$ .

## Results

### Models relating DRC to alkylation-induced cell killing in human lymphoblastoid cell lines

Twenty-four lymphoblastoid cell lines derived from genetically diverse, apparently-healthy individuals were used as a

model system (15). These cell lines have been previously shown to exhibit a broad range of sensitivity to killing by the  $S_N1$ -type alkylating agent MNNG (12), and a DNA cross-link forming alkylating agent, BCNU (10). We have now additionally measured the sensitivity of these cell lines to MMS, an  $S_N2$ -type alkylating agent, for which the predominant cytotoxic lesions induced are 3-methyladenine and 7-methylguanine, and the sensitivity of a subset of the 24 cell lines to the  $S_N1$ -type alkylating chemotherapy agent temozolomide. Temozolomide is regarded as a functional analog of MNNG because it methylates DNA via the same reactive methyldiazonium ion intermediate (16), and temozolomide sensitive cells are also sensitive to MNNG (17).

A broad and continuous range of sensitivity to MNNG (12), temozolomide, BCNU (10), and MMS is observed across the 24 lymphoblastoid cell lines (Fig. 1A and Supplementary Table S1). The cell lines were organized in order of decreasing MNNG sensitivity and assigned to color-coded quartiles to facilitate comparisons with respect to temozolomide, BCNU, and MMS sensitivity. Although MNNG and temozolomide sensitivity were strongly correlated ( $R = 0.81$ ) as expected, MNNG sensitivity was less strongly correlated to BCNU sensitivity ( $R = 0.54$ ) and MMS sensitivity ( $R = 0.49$ ). Thus, consistent with clinical observations, sensitivity to one agent does not necessarily predict sensitivity to other agents, especially when they induce a different spectrum of DNA damage (18, 19).

The relationships among sensitivities to the four DNA damaging agents and previously measured repair capacity in five pathways: NHEJ, HR, MMR, NER, and MGMT were evaluated in the lymphoblastoid cell lines (Fig. 1B and Supplementary Tables S1 and S2; ref. 8). The data in Fig. 1B have been Z-scored to emphasize repair capacity variation among the 24 cell lines. No statistically significant linear correlations were observed among repair capacities for the five reporters (Supplementary Tables S3 and S4), and each cell line has a unique constellation of repair capacities. MGMT activity has previously been shown to correlate with MNNG sensitivity in the 24 cell lines (12). This study, with MGMT activity measured by FM-HCR, confirms this result, and further finds that MGMT activity correlates significantly with sensitivity to killing by temozolomide and BCNU (Supplementary Fig. S3). Pairwise linear correlations between DRC in each individual pathway and sensitivity to killing with DNA damaging agents were evaluated based on  $P$ -values calculated for linear trends, as well as the value of the correlation coefficient  $R$  (Supplementary Tables S5 and S6). A majority of the correlations were found to be stronger when calculated for sensitivity versus the logarithm of DRC. All modeling work was thus carried out using the base 10 logarithm of repair capacities as the predictor variable.

Mathematical models were developed to test whether DRC in multiple pathways is correlated to sensitivity to DNA damaging agents (Supplementary Fig. S1). A simple linear model ( $Y = mx + b$ ) relates MNNG sensitivity to MGMT activity (model #1 in Table 1). The positive slope in this model indicates that a 1 standard deviation increase in MGMT activity leads to a 13 point increase in % control growth (Supplementary Fig. S2). This relationship was expected based on the inverse correlation between MGMT activity and MNNG sensitivity that has been observed previously (12), and presently in Supplementary Tables S4 and S5 and Supplementary Fig. S3. A linear model

DRC and sensitivity data for Coriell lymphoblastoid cell line panel.

**A**, Twenty-four lymphoblastoid cell lines organized (from left to right) in descending order of sensitivity to four different DNA-damaging agents. The colors assigned to bars for each cell line in the top panel (MNNG) by quartile were maintained in the temozolomide (TMZ), BCNU, and MMS panels.

Sensitivity to MNNG and MMS was measured at 72 hours. Sensitivity to BCNU and temozolomide was measured at four doubling times post-exposure.

**B**, Heat map representing Z-scores for relative DNA repair capacity among the 24 lymphoblastoid cell lines (rows) in the five pathways (columns). Purple, cell lines with repair capacity below the mean; yellow, cell lines with repair capacity above the mean; white, cell lines with repair capacity at or near the mean. Z-units are reported at the right side of the figure. Cell lines are ordered by sensitivity to MNNG.

relating MGMT activity to temozolomide sensitivity similarly indicated that an increase in MGMT activity leads to an increase in temozolomide resistance (model #4 in Table 1). A MATLAB script, available in the supplemental information, was used next to generate a MLR model relating Z-scored DRC data in all five DNA repair pathways to cytotoxicity induced by each of the four agents, MNNG, temozolomide, BCNU, and MMS. In these models (#2, #5, #7, and #9 in Table 1), DRC values for each pathway in the 24 cell lines in Fig. 1B served as the five (independent) predictor variables, and the sensitivity of the same 24 cell lines (reported as % control growth in Fig. 1A) was the (dependent) response variable. The resulting MLR models take the form given below in Eq. 2,

$$Y = m_1x_1 + m_2x_2 + m_3x_3 + m_4x_4 + m_5x_5 + b \quad (2)$$

where  $Y$  represents the response variable (MNNG sensitivity) reported as % control growth;  $x_i$  are the DRC predictor variables for the five substrates reported as z-scored log % reporter expression,  $m_i$  are the slopes along the corresponding dimensions, and  $b$  is a constant that represents the  $Y$  intercept. These models (#2, #5, #7, and #9) are denoted as "MLR" in Table 1. The slopes and  $\gamma$ -intercepts of these models are interpreted in the same manner as described above for model #1. For all models, the goodness of fit is reported as the  $R^2$  parameter, and predictive accuracy is reported as the  $R^2_{LOO}$  parameter for predicted sensitivity versus observed sensitivity, calculated from exhaustive leave-one-out cross-validation (Table 1 and Supplementary Fig. S4). An additional parameter in Table 1, AUC, reports how accurately each model predicts temozolomide induced cell killing from DRC for a panel of PDX models of glioblastoma. The application of the models to predict temozolomide sensitivity in glioblastoma is discussed in more detail below.

The models were further refined using a second MATLAB script (available in the Supplementary Information) running the LASSO

algorithm (13) to select combinations of DRC predictor variables to be used for building multiple linear regression (MLR) models of the form given in Eq. 3.

$$Y = m_1x_1 + m_2x_2 \dots + m_nx_n + b. \quad (3)$$

The number and identity of predictor variables ( $n$  [max 5]) used to build the model is established from the results of the LASSO algorithm, which minimizes overfitting by excluding variables that do not improve model performance under cross-validation (13). Models obtained using this approach (#3, #6, #8, and #10) for each DNA damaging agent are denoted as "MLR<sub>L</sub>" in Table 1. The temozolomide MLR<sub>L</sub> retained four pathways (MGMT, HR, MMR, and NER); the MNNG MLR<sub>L</sub> model retained three pathways (MGMT, HR, and MMR). The MLR<sub>L</sub> models for BCNU and MMS retained only a single pathway (MGMT and HR, respectively). As expected, for each alkylating agent, the predictive accuracy of the MLR<sub>L</sub> models was improved relative to the predictive accuracy of the MLR models; this is reflected in higher  $R^2_{LOO}$  values (Table 1), which correspond to better fits in plots of predicted sensitivity versus observed sensitivity for the 24 lymphoblastoid cell lines under leave-one-out cross-validation (Supplementary Fig. S4).

The use of Z-scored DRC data for generating the mathematical models allows for a straightforward interpretation of the slopes ( $m_i$ ) that are associated with each model: the steeper the slope, the more strongly the model responds to a given number of standard deviations about the mean for that particular pathway. A slope of 0 would indicate a model in which drug sensitivity is entirely independent of the DNA repair pathway in question.

#### Sensitivity models for the S<sub>N</sub>1-type alkylating agents temozolomide and MNNG

The MLR models for the S<sub>N</sub>1 alkylating agents MNNG and temozolomide (#2 and #5) are similar in several respects

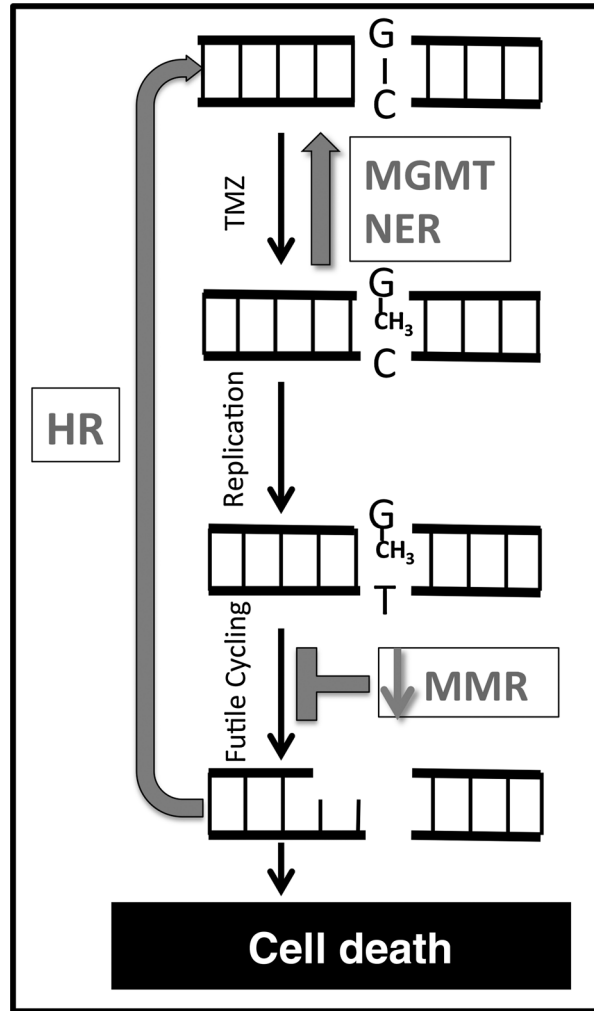

(Table 1). First, the coefficients for MGMT and HR are large and positive in both models, indicating that the models are relatively sensitive to small changes in repair capacity in these pathways, and higher MGMT or HR repair capacity leads to a lower sensitivity to killing with either agent. Second, MMR takes a negative coefficient in both models, indicating that higher MMR capacity leads to higher sensitivity to killing. This aspect of the modeling is borne out in the raw data; higher MMR activity in cell line #6 versus cell line #10 without major differences in other pathways is associated with higher MNNG sensitivity in cell line #6 (Fig. 1). Third, the NHEJ coefficient is the smallest in both models, suggesting that this pathway plays the smallest role in sensitivity to  $S_N1$  type alkylating agents. Finally, the NER coefficient is positive in both models, indicating that higher NER capacity is associated with lower sensitivity to  $S_N1$  alkylating agents. Both the MNNG and temozolomide  $MLR_L$  models (#3 and #6) exclude the NHEJ pathway, further indicating that this pathway does not contribute significantly to sensitivity to either agent for this panel of cells. The  $MLR_L$  models also both retain MGMT, MMR, and HR, but differ in that the temozolomide model also includes NER. To test whether the differences in  $MLR_L$  models (#3 and #6) were due to the inclusion of five additional cell lines in model #6, an MNNG sensitivity model was generated for the same subset of 19 cell lines for which the temozolomide models were generated (not shown). Like model #3, this  $MLR_L$  model also did not include the NER pathway. We infer that the differences in models #3 and #6 are not due to the use of a subset of cell lines as the training population for the temozolomide model. As detailed in the Supplemental Information, these models are consistent with previously established roles for the MGMT, MMR, HR, and NER pathways affecting the sensitivity of cells to killing with  $S_N1$ -type alkylating agents (Fig. 2), although the quantitative contributions of each pathway have not previously been determined.

**Sensitivity models for BCNU and MMS**

The BCNU and MMS sensitivity models are distinguished in several respects from the  $S_N1$  alkylating agent sensitivity models. For both the BCNU and MMS  $MLR$  models (#7 and #9), the MMR coefficient was small (Table 1), and was not retained in the  $MLR_L$  models (#8 and #10), indicating that MMR capacity does not play a major role in determining cellular sensitivity in the models. Both  $MLR_L$  models retain only a single DNA repair pathway, and the MMS  $MLR_L$  model is the only model that excludes the MGMT pathway. The  $MLR_L$  models indicate that HR plays a significant role in determining MMS sensitivity, whereas MGMT activity is the major contributor to BCNU sensitivity. As with the temozolomide and MNNG sensitivity models, models #7-10 are consistent with previously established roles for DRC affecting the cellular MMS and BCNU sensitivity (see Supplemental Information).

**Measuring DRC in glioblastoma**

The temozolomide and MNNG models suggest that relatively small changes in MGMT, MMR, HR, and NER could be responsible for changes in sensitivity to killing with  $S_N1$ -type alkylating agents in cancer cells. To test whether relationships between DRC and temozolomide sensitivity in lymphoblastoid cell lines also apply to glioblastoma, we measured changes in DRC that accompany temozolomide resistance acquired *in vivo* for several paired

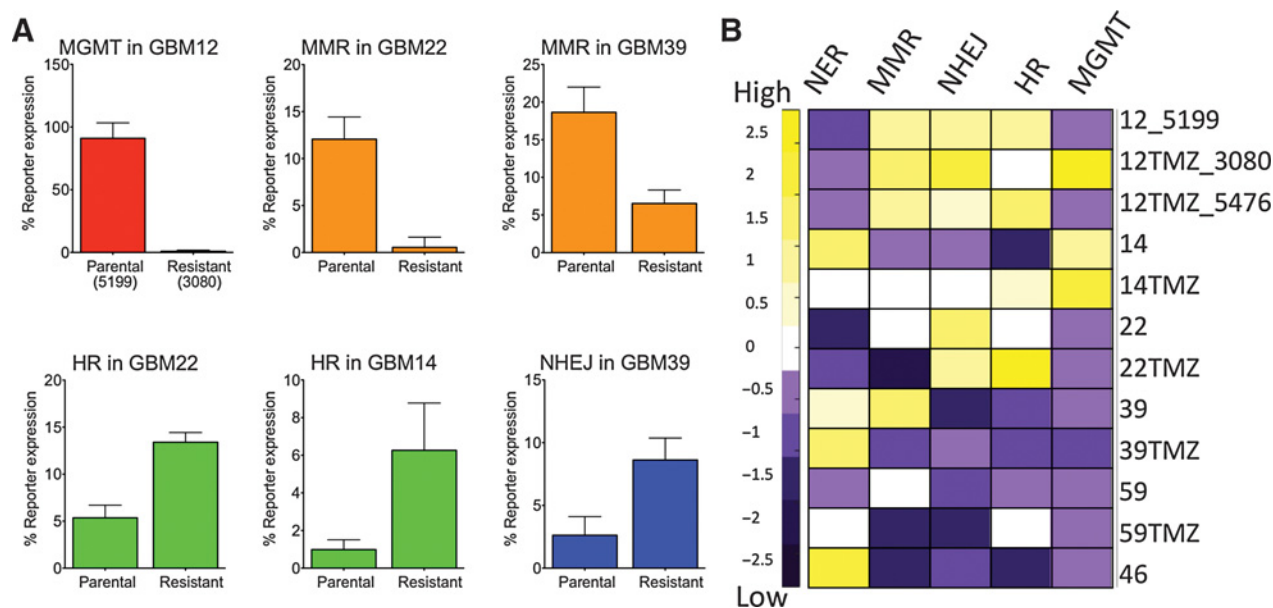

**Figure 2.** Model for temozolomide (TMZ) resistance mechanisms mediated by DNA repair capacity. Double-stranded DNA is represented by parallel black lines. A normal G:C base pair is indicated at the top of the figure. Strand breaks are indicated as gaps in the black lines. Gray arrows and text indicate DNA repair processes that mediate sensitivity and resistance to DNA methylation damage.

sensitive and resistant PDX models of glioblastoma (Fig. 3 and Supplemental Table S7), as well as one PDX model (GBM46) innately temozolomide-resistant model (9). The parental PDX models (GBM12, GBM14, GBM22, GBM39, GBM59, and GBM46) were previously classified as "resistant" or "sensitive" to temozolomide based on whether temozolomide treatment produces a statistically significant survival benefit *in vivo* (20), and statistically significant increases in temozolomide resistance in the PDX models (GBM12TMZ\_3080, GBM12TMZ\_5476, GBM14TMZ, GBM39TMZ, and GBM59\_TMZ) have been measured *in vitro* either by neurosphere formation or by cell proliferation assays (21).

Strikingly, we observe statistically significant changes in DRC that are consistent with the relationship between DRC and  $S_N1$ -type alkylating agent sensitivity suggested by the MNNG and temozolomide sensitivity models (Table 1). In cell lines that

**Figure 3.**

DNA repair capacity measured using FM-HCR in glioblastoma cells. **A**, Statistically significant changes in DRC in PDX models of acquired temozolomide resistance. Note that for the MGMT assay, lower percentage of reporter expression corresponds to higher MGMT activity. Error bars represent the standard deviation of at least three measurements. **B**, A heat map representing Z-scored DNA repair capacity in five pathways (columns) for all 12 glioblastoma models (rows; numbers refer to the parental GBM lines and the "TMZ" suffix refers to acquired temozolomide resistance lines labeled "Resistant" in panel **A**). Purple, cell lines with repair capacity below the mean; yellow, cell lines with repair capacity above the mean; white, cell lines with repair capacity at or near the mean.

acquired temozolomide resistance, we observed increased MGMT activity (GBM12/GBM12TMZ\_3080), increased HR capacity (GBM14/GBM14TMZ and GBM22/GBM22TMZ), or decreased MMR capacity (GBM22/GBM22TMZ and GBM39/GBM39TMZ) relative to the temozolomide-sensitive parental cell lines (Fig. 3A). Statistically significant changes in NHEJ (GBM39/GBM39TMZ) were also observed (Fig. 3A). Although the differences were not statistically significant, NER activity trended higher in all of the acquired resistance models relative to their corresponding parental lines, except for GBM14. A trend toward reduced MMR and elevated HR capacity was also observed in GBM59TMZ relative to GBM59; however, these apparent changes likewise did not reach statistical significance (Fig. 3B). Overall, the data indicate that the relationship between DRC and sensitivity to temozolomide and MNNG in lymphoblastoid cell lines (Table 1) are applicable to temozolomide sensitivity in glioblastoma.

#### Applying mathematical modeling to predict sensitivity to temozolomide in glioblastoma

The ability of mathematical models to classify PDX models of glioblastoma as temozolomide sensitive or temozolomide-resistant was tested. ROC plots for a subset of the models are presented in Fig. 4A. The MLR<sub>L</sub> model trained using temozolomide sensitivity in lymphoblastoid cell lines (#6) is the best predictor of temozolomide sensitivity in glioblastoma (AUC = 0.86). The MLR<sub>L</sub> model generated from DRC for sensitivity to MNNG (#3) yielded an AUC of 0.74. Predictions using a model for MMS sensitivity yielded an AUC = 0.71 (model #10), and a model generated for BCNU sensitivity (model #8) barely outperformed random chance for this panel of PDX models (AUC = 0.54).

The best model (#6) also correctly predicts temozolomide resistance in the acquired resistance models relative to the corresponding parental cell lines in all of the paired PDX models (Fig. S5). Importantly, using DRC data for multiple pathways in glioblastoma cell lines improves the predictive accuracy for temozolomide sensitivity models versus those that include only the MGMT pathway. MGMT activity measured by FM-HCR was correlated to methylation status ( $R = 0.61$  and Supplementary Fig. S6), but the extent of promoter methylation varied over a ~10-fold range among glioblastoma lines that all had very low MGMT activity, consistent with previous observations indicating that widely used MGMT tumor promoter methylation assays may not accurately predict MGMT transcript levels and activity (22). When cells are ranked according to temozolomide sensitivity as predicted by model #4, which includes only MGMT activity (Fig. 4B), two temozolomide-resistant cell lines, GBM22TMZ and GBM39TMZ, are predicted to be the most sensitive, with predicted % control growth ~10%, and AUC = 0.54. By contrast, when PDX models are ranked according to temozolomide sensitivity predicted by model #6, which takes MGMT, MMR, HR, and NER into account, the predicted response across the glioblastoma cell lines is much more accurate relative to previously measured sensitivity (20, 21); the improved accuracy can be appreciated both qualitatively (Fig. 4C) and quantitatively (AUC = 0.86).

#### Using DRC-based modeling to predict effectiveness of therapy with temozolomide *in vivo*

The ultimate goal of predicting the sensitivity of glioblastoma cells to S<sub>N</sub>1 alkylating agents is to generate a metric that could potentially guide cancer therapy decisions. This goal requires that repair capacity *in vitro* predicts therapeutic response *in vivo*, where

**Figure 4.**

Classification of glioblastoma PDX models as temozolomide (TMZ) sensitive or temozolomide resistant. **A**, Plots showing ROC curves (black lines) for sensitivity models for BCNU (model #8); MMS (#10); MNNG (#3); temozolomide (#6). The numbers refer to models detailed in Table 1. AUC is calculated from the area under the ROC curves and can adopt values between 0 (all samples are classified incorrectly) and 1 (all samples are classified correctly). The dotted red line represents a theoretical ROC curve for a model that classifies samples randomly (AUC = 0.5). **B**, PDX models organized in ascending order of predicted percent control growth as calculated from model #4. Lower predicted percent control growth represents higher predicted sensitivity to temozolomide. **C**, PDX models organized in ascending order of predicted percent control growth as calculated from model #6. Temozolomide sensitivity was determined previously for the PDX models; black bars, PDX models that temozolomide resistant (TMZ<sup>R</sup>); red bars, PDX models that are TMZ sensitive (TMZ<sup>S</sup>). A Mann-Whitney *U* test indicated that the two populations (TMZ<sup>R</sup> and TMZ<sup>S</sup>) were significantly different in **C** ( $P = 0.03$ ), but not in **B**.

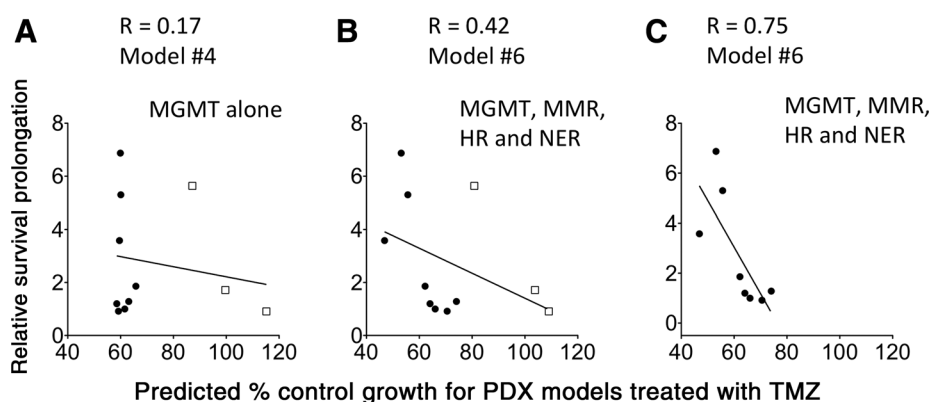

the sensitivity of cancer cells to DNA damaging therapies can be strongly influenced by tumor microenvironment (23). The PDX models for which we have measured DRC profiles have previously been shown to exhibit a broad range of responsiveness to *in vivo* temozolomide therapy, measured by relative survival prolongation of tumor bearing mice treated with temozolomide versus tumor bearing mice receiving placebo (21). Relative survival prolongation is calculated by dividing the median survival time for treated mice by the median survival time for untreated mice; larger values reflect longer survival in treated mice relative to untreated mice.

To test whether the DRC profiles measured using FM-HCR in cultured cells predict temozolomide therapy effectiveness *in vivo*, relative survival prolongation in temozolomide-treated PDX mouse models was compared against temozolomide sensitivities predicted using the models in Table 1. Sensitivities predicted using a model that includes MGMT activity alone (model #4) are only weakly correlated to relative survival prolongation, and PDX models with low MGMT expression (black dots in Fig. 5A) range from highly responsive to completely refractory to treatment with temozolomide. A stronger correlation is observed between survival prolongation and predicted sensitivity calculated for the PDX models using a temozolomide sensitivity model that includes MGMT, MMR, HR, and NER (model #6; Fig. 5B). These results indicate that

relatively small changes in HR, MMR, and NER capacity collectively contribute to changes in glioblastoma temozolomide sensitivity, and that the resistance mechanisms detailed in Fig. 2 operate *in vivo*. When the analysis is restricted to MGMT-deficient PDX models, the correlation between relative survival prolongation and the combined DRC score is even stronger (Fig. 5C). The strong correlation in MGMT-deficient cells underscores the importance of DNA repair pathways other than MGMT in determining the effectiveness of temozolomide therapy. Importantly, these results demonstrate that DRC measurements carried out in cells *in vitro* can at least partially predict therapeutic response *in vivo*.

## Discussion

The ability to choose the optimal therapy for each patient would have tremendous ramifications for cancer treatment. Advance knowledge of whether a particular therapy will be effective would increase the likelihood of achieving the primary goal of killing cancer cells, and avoid subjecting patients to unnecessary treatments that cause serious side effects and increase the risk of additional cancers (24–26). DRC continues to emerge as an important determinant for the response of cancer cells to therapy (27), making accurate DRC assessments a key goal for precision medicine (7).

**Figure 5.**

Correlation between relative survival prolongation for PDX mouse models treated with temozolomide (TMZ) and predicted percent control growth for PDX models treated with temozolomide calculated from model #4 (A) or model #6 (B and C). In C, PDX models were restricted to those expressing low levels of MGMT (black dots). Cells with low MGMT levels were defined as those for which the average percentage of reporter expression for the MGMT assay was at least 50%; this value of percentage of reporter expression was observed previously for a cell line that is known to be MGMT deficient (TK6). PDX models with higher levels of MGMT reporter expression are represented with open squares.

The potential to predict temozolomide sensitivity from DRC in multiple pathways underscores need to measure MGMT, HR, NER, and MMR activity in order to make the most robust DNA repair-based predictions regarding the effectiveness of temozolomide therapy. However, direct measurements of DNA repair activity in clinical samples has been limited because previous methods were cumbersome, time consuming, incompatible with multiplexing, and in most cases did not report on the functional status of repair (7). Tumor MGMT status is considered a strong predictor of therapeutic response in glioblastoma (28), and clinicians use MGMT promoter methylation assays or in some cases immunohistochemical analysis of excised tumor tissue to infer MGMT activity in glioblastoma (29). Nevertheless, concerns remain about standard clinical MGMT assays that unlike FM-HCR, do not directly measure MGMT activity; immunohistochemical analysis is subject to individual bias (30), and although MGMT activity was, as expected, inversely correlated to MGMT promoter methylation in the glioblastoma lines in this study (Supplementary Fig. S6), the high degree of variability in the extent of promoter methylation among MGMT-deficient glioblastoma lines adds to existing evidence that promoter methylation status is not always a reliable measure of tumor MGMT activity (9, 22). Similarly, microsatellite instability assays are used to assess MMR status in clinical samples, but this approach is not quantitative and may not report minor changes in MMR capacity that are sufficient for temozolomide resistance (31, 32). Several approaches have been taken to estimate HR capacity in cancer cells (33), but they rely on transcriptional profiling and mutational signatures that may not predict the functional status of the HR pathway, and are unlikely to detect small differences in functional activity. Finally, unscheduled DNA synthesis has long been used as a method of estimating NER capacity in patient cells (34), but is relatively laborious. By contrast, FM-HCR assays provide a rapid functional assessment of DRC in key pathways that we have shown are useful predictors of temozolomide sensitivity in lymphoblastoid and PDX lines.

This work has been focused on modeling temozolomide sensitivity in glioblastoma, but the fundamental principles governing resistance to DNA-damaging agents, particularly

those driven by relative changes in DRC, are expected to be applicable to multiple agents and multiple cell types. Strikingly, a model trained using DRC and temozolomide sensitivity data for lymphoblastoid cells in culture accurately predicted temozolomide sensitivity of glioblastoma cells treated in mouse PDX models. Additional cell-autonomous therapy resistance mechanisms, including changes in DNA damage signaling (35), damage detoxification mechanisms (36), and drug efflux pumps are expected to complement DNA repair-based resistance mechanisms (37). Single cell-based assays for processes that contribute to resistance, such as FM-HCR, hold the major advantage of being amenable to identifying small, therapy-resistant subpopulations within a tumor, which can expand and emerge as a resistant tumor following treatment (38). Therefore, models integrating FM-HCR assays for DNA repair-based resistance mechanisms with cell-based functional assessments of other therapy resistance mechanisms hold promise for further enhancing predictions of therapy response and advancing personalized cancer treatment.

In summary, our results indicate that temozolomide resistance in cancer cells is associated with differences in repair capacity in at least four DNA repair pathways (MMR, HR, NER, and MGMT), and that a combined DNA repair score derived from FM-HCR assays provides a more robust prognostic biomarker than MGMT activity alone for temozolomide therapy.

#### Disclosure of Potential Conflicts of Interest

J.N. Sarkaria reports receiving a commercial research grant from Novartis, Basilea, Cavion, Curtana, Genentech, Sanofi, Beigene, Lilly, Glaxo-Smith-Kline, Peloton, Glionova, and Bristol-Myers Squibb Pharmaceuticals. No potential conflicts of interest were disclosed by the other authors.

#### Authors' Contributions

**Conception and design:** Z.D. Nagel, S.K. Gupta, P. Mazzucato, D.A. Lauffenburger, LD. Samson

**Development of methodology:** Z.D. Nagel, G.J. Kitange, B.A. Joughin, I.A. Chaim, LD. Samson

**Acquisition of data (provided animals, acquired and managed patients, provided facilities, etc.):** Z.D. Nagel, G.J. Kitange, S.K. Gupta, J.N. Sarkaria, LD. Samson

**Analysis and interpretation of data (e.g., statistical analysis, biostatistics, computational analysis):** Z.D. Nagel, S.K. Gupta, J.N. Sarkaria, LD. Samson  
**Writing, review, and/or revision of the manuscript:** Z.D. Nagel, G.J. Kitange, S.K. Gupta, B.A. Joughin, I.A. Chaim, D.A. Lauffenburger, J.N. Sarkaria, LD. Samson

**Administrative, technical, or material support (i.e., reporting or organizing data, constructing databases):** P. Mazzucato, LD. Samson

**Study supervision:** LD. Samson

## Acknowledgments

The authors thank Rebecca Fry, Brad Hogan, and Meriem Sefta (MIT) for help with measuring MMS sensitivity and temozolomide sensitivity in the Coriell
