Opioid-induced Respiratory Depression Is Only Partially Mediated by the preBötzinger Complex in Young and Adult Rabbits In Vivo

Astrid G. Stucke, M.D., Justin R. Miller, Ph.D., Ivana Prkic, M.D., Edward J. Zuperku, Ph.D., Francis A. Hopp, M.S., Eckehard A. E. Stuth, M.D.

ABSTRACT

Background: The preBötzinger Complex (preBC) plays an important role in respiratory rhythm generation. This study was designed to determine whether the preBC mediated opioid-induced respiratory depression at clinically relevant opioid concentrations in vivo and whether this role was age dependent.

Methods: Studies were performed in 22 young and 32 adult New Zealand White rabbits. Animals were anesthetized, mechanically ventilated, and decerebrated. The preBC was identified by the tachypneic response to injection of Nω-homocysteic acid. (1) The μ-opioid receptor agonist [d-Ala2,N-Me-Phe4,Gly-ol]-enkephalin (DAMGO, 100 μM) was microinjected into the bilateral preBC and reversed with naloxone (1 mM) injection into the preBC. (2) Respiratory depression was achieved with intravenous remifentanil (0.08 to 0.5 μg kg⁻¹ min⁻¹). Naloxone (1 mM) was microinjected into the preBC in an attempt to reverse the respiratory depression.

Results: (1) DAMGO injection depressed respiratory rate by 6 ± 8 breaths/min in young and adult rabbits (mean ± SD, P < 0.001). DAMGO shortened the inspiratory and lengthened the expiratory fraction of the respiratory cycle by 0.24 ± 0.2 in adult and young animals (P < 0.001). (2) During intravenous remifentanil infusion, local injection of naloxone into the preBC partially reversed the decrease in inspiratory fraction/increase in expiratory fraction in young and adult animals (0.14 ± 0.14, P < 0.001), but not the depression of respiratory rate (P = 0.19). PreBC injections did not affect respiratory drive. In adult rabbits, the contribution of non-preBC inputs to expiratory phase duration was larger than preBC inputs (3.5 [−5.2 to 1.1], median 25 to 75%, P = 0.04).

Conclusions: Systemic opioid effects on respiratory phase timing can be partially reversed in the preBC without reversing the depression of respiratory rate. (Anesthesiology 2015; 122:1288-98)

OPIOID-INDUCED respiratory depression poses an important limitation for the use of opioids in perioperative pain control. This side effect is particularly pronounced in premature and young infants, which has been attributed to reduced opioid metabolism and a less effective blood–brain barrier. However, divergent results from adult canine and neonatal rat preparations point to important functional developmental differences in respiratory effects of opioids.

Studies investigating opioid effects on respiration have focused on the preBötzinger Complex (preBC) as the main region of respiratory rhythm–pattern generation and by default as the main site of opioid-induced respiratory depression. Neuronal in vitro studies support a role of the preBC in opioid-induced respiratory depression, but results from adult in vivo preparations are contradictory.

While microdialysis of the μ-opioid receptor agonist [d-Ala2,N-Me-Phe4,Gly-ol]-enkephalin (DAMGO, 5 μM) into the brainstem of adult rats led to bradypnea, localized microinjection of DAMGO (100 μM) into the preBC of adult dogs in vivo led to tachypnea. In both studies, local agonist concentrations were far higher (μM–mM) than the low nanomolar tissue concentrations generally achieved in vivo.
during systemic, intravenous opioid use (~20 nM).\textsuperscript{10} When clinically relevant opioid doses were given, respiratory slowing from intravenous fentanyl (5 μg/kg) was prevented in adult rats by microdialysis of naloxone into the brainstem administered for 45 min before fentanyl,\textsuperscript{9} but in adult dogs, microinjection of naloxone directly into the functionally identified preBC region did not reverse respiratory depression from intravenous remifentanil.\textsuperscript{5} We contend that these discrepant findings were due to the fact that localized microinjection in the dog solely affected the preBC while microdialysis of DAMGO and naloxone in rats was more diffuse and affected additional brainstem areas involved in respiratory rate (RR) control.\textsuperscript{4} However, even if the preBC was not the site of opioid-induced respiratory depression in adult animals \textit{in vivo},\textsuperscript{5} respiratory depression from opioids was clearly observed in neonatal \textit{in vitro} preparations that included only the preBC and used “near-clinical” agonist concentrations.\textsuperscript{6,7} Thus, developmental differences in clinical opioid effect on respiratory control sites seem to exist. A recently published point-counterpoint debate on this topic highlighted the ongoing controversy and emphasized the clinical relevance of identifying the site of opioid effect.\textsuperscript{11–14}

The current study was designed to gain a comprehensive understanding of opioid effects on the preBC and respiratory pattern generation. We have developed a decerebrate rabbit model that allows studying developmental differences in respiratory control at the neuronal level in functionally defined areas of the brainstem in young and adult animals \textit{in vivo}. Protocol 1 tested whether injection of pharmacological concentrations of the μ-opioid receptor agonist DAMGO into the preBC affected RR and pattern. Protocol 2 tested whether the depression of RR and the change in respiratory pattern that resulted from systemic opioid infusion at clinically relevant concentrations could be antagonized by localized injection of the opioid antagonist naloxone into the preBC. We hypothesized that there were developmental differences in the role of the preBC in clinical, opioid-induced respiratory depression between young and adult rabbits.

**Materials and Methods**

**Surgical Procedures**

This research was approved by the subcommittee on animal studies of the Zablocki Veterans Affairs Medical Center, Milwaukee, Wisconsin, in accordance with provisions of the Animal Welfare Act, the Public Health Service Guide for the Care and Use of Laboratory Animals, and Veterans Affairs policy. Adult (3 to 4 kg) and young (2 to 3 weeks, 110 to 550 g) New Zealand White rabbits of either sex were induced with 5 vol% sevoflurane \textit{via} facemask. Animals were ventilated \textit{via} tracheotomy with an anesthesia machine (Ohmeda CD; GE, Datex Ohmeda, USA) or if weight was below 400 g, with a small animal ventilator (SAR-830 ventilator; CWE, USA). Anesthesia was maintained with 1 to 2% (young) or 1.5 to 3% (adult) isoflurane. Inspiratory oxygen fraction, expiratory carbon dioxide concentration, and inspiratory isoflurane concentration were continuously recorded with an infrared analyzer (POET II; Criticare Systems, USA). Skin was infiltrated with lidocaine 1% before each skin incision. Femoral arterial and venous catheters were used for blood pressure monitoring and infusion of solutions, respectively. Care was taken to increase anesthetic depth for any signs of “light anesthesia,” for example, increase in blood pressure or lacrimation. Lactated Ringer’s solution with 2 μg/ml epinephrine was continuously infused at 1 ml/h. At this rate, the infusion did not result in appreciable changes in heart rate and blood pressure. Infusion rate was increased as needed to counteract or prevent hypotension in response to drug injections or from blood loss. The animal was maintained at 37.0° ± 0.5°C with a warming blanket. The animal was placed in a stereotaxic frame (David Kopf Instruments, USA), and blunt precollateral decerebration with complete removal of the forebrain was performed through a parietal craniotomy. After decerebration, isoflurane was discontinued or continued at subanesthetic levels (0.3 to 0.4 Vol%) for blood pressure control. Isoflurane concentration was not changed throughout the experimental protocol. The brainstem was exposed \textit{via} occipital craniotomy, and partial removal of the cerebellum and the volatile anesthetic was discontinued. Animals were paralyzed with vecuronium (initially 1 mg/kg and redosed as needed) to avoid motion artifacts during neural–neuronal recording. The vagal nerves were left intact. The phrenic nerve was recorded with fine bipolar electrodes through a posterior neck incision. Throughout the experiment animals were ventilated with a hypoxic gas mixture (FiO₂, 0.6) to achieve functional denervation of the peripheral chemoreceptors and at mild hypocapnia (expiratory carbon dioxide, 45 to 55 mmHg) to ensure sufficient respiratory drive (i.e., above the apneic threshold) even during systemic opioid infusion. Blood pressure was maintained stable throughout the protocols by adjusting the intravenous infusion rate. At the end of the experiment, the animals were euthanized with intravenous potassium chloride. In a subgroup of animals, the microinjection site was marked with pontamine blue dye and the brainstem was removed after euthanasia and fixed for histological analysis.

**Neuronal Recording, Drug Application, Measured Variables, and Data Analysis**

All neuronal recording and microinjection techniques have been well established by our research group and have been previously described in detail.\textsuperscript{15,16} In short, extracellular neuronal recordings were obtained using multibarrel micropipettes (20 to 40 μm tip diameter) consisting of three drug barrels and a recording barrel containing a 7-μm thick carbon filament. Barrels were filled with the glutamate agonist D,L-homocysteic acid (DLH, 1 mM), the μ-opioid receptor agonist DAMGO (100 μM), and the opioid receptor antagonist naloxone (1 mM), which were dissolved in artificial cerebrospinal fluid. The microinjected volume was determined...
Stucke et al.

Opioid Effects on the Respiratory Pattern Generator

via height changes in the meniscus in the respective pipette barrel with a 100× monocular microscope and calibrated reticule (resolution, ~3.5 nl). Respiratory neuron subtypes were classified according to their discharge patterns and their temporal relationships relative to the phrenic neuron. The neuronal and phrenic neural activity and pressure microejection marker signals were recorded using a digital acquisition system. These variables were also continuously displayed and recorded along with the phrenic neuronogram, inspiratory time, expiratory time, discharge rate-meter, arterial blood and tracheal pressures, airway carbon dioxide, and oxygen concentration on a computerized chart recorder (Powerlab/16SP; ADInstruments, Australia). Post hoc analysis averaged respiratory cycles from the phrenic neuronogram. Before and after drug injection, steady-state conditions were obtained for respiratory parameters. Between 10 and 50 consecutive respiratory cycles were averaged over 1 to 2 min with the number of cycles dependent on the RR. We determined peak phrenic activity (PPA), RR, and inspiratory (Ti) and expiratory (Te) duration. Since changes in PPA closely reflect changes in respiratory tidal volume but the absolute value does not correspond with the absolute tidal volume,17 PPA was normalized to control values for all calculations. An estimate of respiratory drive was calculated as the rise in phrenic nerve amplitude during the inspiratory phase (i.e., PPA/Ti). In order to discern the opioid effects on inspiratory and expiratory phase timing, we calculated the inspiratory fraction (Ti/Ttot) and expiratory fraction (Te/Ttot) of the total respiratory cycle (Ttot), that is, Ttot = Ti + Te and Ti/Ttot + Te/Ttot = 1.

**Sample Size and Statistical Analysis**

Statistical procedures on the pooled data were performed using SigmaPlot 11 (Systat Software, USA). Sample size was based on published in vivo studies using similar protocols. These studies had used 4 to 9 rats per protocol4,5 and 10 to 21 dogs per protocol.4,5 Initial data analysis was performed after 5 to 6 animals, and additional experiments were added for a protocol to either confirm or refute nonsignificant trends in the data.18 Data sets were tested for normal distribution (Kolmogorov–Smirnov test). Statistical tests were performed on raw data except for respiratory drive, where PPA is measured in arbitrary units and normalization to control is necessary to allow for comparison between animals. The effects of opioid agonists–antagonists on all respiratory parameters (RR, PPA, Ti, Te, PPA/Ti, Ti/Ttot) were determined separately for young and adult animals using one-way, repeated-measures ANOVA with Holm–Sidak correction for multiple comparisons for normally distributed data and Friedman repeated measures ANOVA on ranks with Tukey test for pairwise multiple comparisons for not normally distributed data. Differences between opioid agonist–antagonist effects between young and adult animals were determined for RR, PPA/Ti, and Ti/Ttot using two-way repeated measures ANOVA with treatment and developmental age as factors. To compare preBC and non-preBC inputs to Ti and Te, which were not normally distributed, Kruskal–Wallis ANOVA on ranks with Dunn method for multiple comparisons was used to test for differences between inputs and age groups. Two-tailed tests were performed to test for significant differences without regard to direction. P values were not adjusted in response to the sequential testing that was conducted during the study. Differences were considered significant for P value of less than 0.05. Values are expressed as mean ± SD or median (25 to 75% range) as appropriate.

**Location of the preBC Region**

The preBC region was located according to three criteria: (1) Stereotoxic coordinates: Stereotoxic coordinates were available in the literature for adult rabbits.19,20 To establish the location in young rabbits, we performed multiple preliminary experiments recording neuronal activity in a grid-wise fashion rostralateral of obex. The ventral respiratory column was identified by recording respiratory-related neuronal discharge activity. Within the ventral respiratory column, the location of the preBC was determined using neuron types based on discharge patterns and DLH injection. We then injected pontamine blue dye into the preBC and verified the location histologically as immediately ventrolateral to the nucleus ambiguous.7 On average, in young animals the preBC was located at 1.0 ± 0.5 mm rostral of obex, 2.2 ± 0.4 mm lateral of midline, and 2.1 ± 0.2 mm ventral of the dorsal surface with part of the variance explained by differences in animal weight. (2) Mixture of inspiratory and expiratory neurons: The preBC is considered the part of the ventral respiratory column that contains a mixture of propriobulbar inspiratory and expiratory neuronal subtypes.21 This is in keeping with its presumptive role in respiratory rhythm generation.22 (3) Tachypneic response to injection of DLH: The tachypneic response to microinjection of DLH (fig. 1) has been accepted as a functional marker for the preBC by investigators using various animal models.23,24 The tachypneic response to a glutamate agonist emphasizes the importance of this area in respiratory pattern generation. The preBC was defined as the area where DLH caused the largest increase in RR or, when the increase was identical in two neighboring areas, the area where the tachypneic effect lasted longest (fig. 1).

**Protocol 1: Effects of Pharmacological Opioid Concentrations on the preBC in Young and Adult Rabbits**

For all protocols, the experimenters were not blinded to the experimental conditions. Direct injection of high concentrations of the μ-opioid agonist DAMGO (100 μM) in small volumes into the preBC was performed to allow direct comparison with studies in other species (rodents and dogs) using this approach in in vitro and in vivo preparations. This protocol established the changes in respiratory pattern that could be achieved with maximal opioid receptor activation in the preBC. In addition, this protocol determined the drug
The preBötzinger Complex (preBC) was functionally identified as the area with recorded respiratory activity where d,l-homocysteic acid injection caused maximal tachypnea and had the fastest onset and longest effect as determined from the phrenic neurogram.

**Protocol 2: Effects of Clinical Opioid Concentrations on the preBC in Young and Adult Rabbits**

Recognizing that pharmacological (i.e., supraclinical) concentrations of µ-opioid receptor agonists may have different effects on the individual components of the respiratory network than tissue concentrations achieved with clinically relevant drug doses, we infused the µ-opioid agonist remifentanil intravenously at “clinical relevant” dose rates for rabbits. We then determined whether the resulting respiratory depression could be antagonized by localized injections of naloxone into the preBC, that is, whether the preBC was the site of the opioid effect.

The preBC was identified on both sides of the brainstem as described in Location of the preBC Region section. Then, remifentanil was infused intravenously at 0.08 to 0.5 μg kg⁻¹ min⁻¹ until peak phrenic amplitude and RR were depressed by approximately 50%. Remifentanil was chosen since its rapid metabolism by plasma and tissue esterases ensures quick onset of the maximal dose effect and a context-sensitive half-life that is short (~4 min) and independent of the duration of the infusion. After reaching steady-state respiratory depression for at least 5 min, naloxone (140 nl in young and 350 nl in adults) was injected bilaterally at the coordinates of maximal DLH effect as well as in the dorsoventral center of respiratory activity 1 mm rostral and 1 mm caudal of this location. This volume of naloxone was based on results from protocol 1 where it had reliably reversed the effects of DAMGO injection. Approximately 10 min after the last localized naloxone injection, naloxone (30 to 80 μg/kg) was given intravenously to completely reverse the remifentanil effect. Only then was the remifentanil infusion terminated. To avoid confounding residual drug effects, only one protocol was performed per animal.

**Protocol 3: Potential Endogenous Opioid Effects on the preBC in Young and Adult Rabbits**

To rule out that any naloxone effect observed in protocol 2 was due to a reversal of endogenous opioid activity in the preBC rather than to a reversal of the intravenous remifentanil effect, we injected naloxone (140 nl in young and 350 nl in adults) into the preBC as well as in the dorsoventral center of respiratory activity 1 mm rostral and 1 mm caudal...
of this location. This protocol was performed in a separate set of animals without remifentanil infusion. Ten minutes after the last injection, naloxone (30 to 80 μg/kg) was given intravenously to completely reverse any potential endogenous opioid effect.

Model to Assess Non-preBC and preBC Contributions to Phase Timing
We developed a hypothetical model of preBC and non-preBC inputs to the respiratory pattern that can account for the opioid-induced pattern changes observed in protocols 1 and 2. The model assumes that phase timing, that is, the duration of inspiratory and expiratory phase within the respiratory cycle depends on three factors: (1) intrinsic timing properties of the respiratory neuronal network generating an inspiratory (T½) and expiratory phase (T½), (2) non-preBC input affecting the inspiratory (Fnon) and expiratory (Fnon) phase, and (3) preBC input affecting the inspiratory (FpreBC) and expiratory (FpreBC) phase. These inputs can either increase or decrease the respective phase duration. The model further assumes that both, preBC and non-preBC inputs, are reduced by systemic opioid agonists (e.g., intravenous remifentanil [r]) and that the opioid effect on the preBC inputs is fully reversed by local injection of the opioid antagonist naloxone into the preBC. For details on the computation, please see the appendix. Mean values for T½ and T½ obtained from protocol 2 were used to develop the model including determination of the polarity of the preBC and non-preBC inputs. The model was then used to calculate the preBC and non-preBC inputs for each individual animal. Pooled values are presented in the Results section.

Results
Protocol 1: Effects of Pharmacological Opioid Concentrations on the preBC in Young and Adult Rabbits
Eight protocols were completed in young rabbits (13 to 23 days, 200 to 500 g). An example is shown in figure 2A. Univariate analysis of the effects of DAMGO injection into the preBC showed a significant depression of RR (−9.4 ± 5.7 breaths/min, P < 0.001). This was due to an increase in

![Figure 2: Protocol 1. (A) Phrenic neurogram (PNG) of a young rabbit (20 days, 325 g). Bilateral [d-Ala2,N-Me-Phe4,Gly-ol]-enkephalin (DAMGO) microinjection (70 nl) into the preBötzinger Complex plus 1 mm rostral and 1 mm caudal to this area depressed peak phrenic amplitude and respiratory rate to the point of apnea. Local injection of naloxone (NAL) at the same coordinates reversed the DAMGO effect. (B–D) Effects of localized microinjection of the μ-opioid agonist DAMGO in pharmacological concentrations (100 μM) into the bilateral preBötzinger Complex and reversal with localized injection of the opioid antagonist naloxone (1 mM). Pooled data are shown separately for 16 adult (blue) and 8 young (red) rabbits. Box plots show median and range (10%, 25%, 75%, and 90%); individual data points are superimposed. Levels of significance reflect the results of the 2-way ANOVA. (B) DAMGO injection depressed respiratory rate. (C) Respiratory drive, calculated as PPA/T½, was not affected. (D) DAMGO injection depressed inspiratory fraction (T½/Ttotal). The effects in young and adult animals were not significantly different. n.s. = not significant; PPA = peak phrenic activity; T½ = inspiratory duration; Ttotal = duration of the respiratory cycle.](https://example.com/figure2.png)
Te (4.2 ± 4.9 s, \( P = 0.04 \)) while Ti was unchanged (-0.1 [-0.4 to 0.15] s, \( P = 0.285 \)). DAMGO injection increased the duration of the respiratory cycle (Ttot) by 3.6 ± 3.8 s (\( P = 0.03 \)). The inspiratory fraction (Ti/Ttot) was reduced from 0.5 ± 0.1 to 0.3 ± 0.1 (\( P < 0.001 \)), and thus, the expiratory fraction (Te/Ttot) was increased from 0.5 ± 1 to 0.7 ± 0.1 (\( P < 0.001 \)). PPA was not significantly changed (-2.0 ± 3 a.u., \( P = 0.074 \)), and respiratory drive, calculated as PPA/Ti, was not affected (-8 ± 16%, \( P = 0.49 \)). All DAMGO effects were reversed by local naloxone injection.

Sixteen protocols were completed in adult rabbits (3.8 to 4.8 kg). Univariate analysis showed that DAMGO injection into the preBC caused respiratory responses with large variability: Overall, DAMGO did not change RR (-3.8 ± 7.8 breaths/min, \( P = 0.11 \)). There was a significant increase in Te (1.1 [0.2 to 5.6] s, \( P < 0.05 \)), and Ti was significantly reduced (-0.65 [-0.24 to -1.3] s, \( P < 0.05 \)). Overall respiratory cycle duration was unchanged (0.1 [-0.4 to 4.8] s, \( P = 0.48 \)), but inspiratory fraction was decreased from 0.6 ± 0.2 to 0.4 ± 0.3 (\( P < 0.001 \)) and expiratory fraction was thus increased from 0.4 ± 0.2 to 0.6 ± 0.3 (\( P < 0.001 \)). Since respiratory drive was not significantly changed (23 ± 36%, \( P = 0.09 \)), the decrease in Ti resulted in a decrease in PPA (-4.1 ± 6.6 a.u., \( P = 0.03 \)). Data for Ti, Te, Ttot, and PPA and the results of the univariate analysis are not shown in figures.

The interaction of the DAMGO effect on the preBC and animal age was analyzed for RR, respiratory drive, and inspiratory fraction using 2-way, repeated measures ANOVA. DAMGO injection significantly depressed RR by 6 ± 8 breaths/min (\( P = 0.001 \), fig. 2B), did not affect respiratory drive (-12 ± 33%, \( P = 0.09 \), fig. 2C), but decreased inspiratory fraction (-0.24 ± 0.2, \( P < 0.001 \), fig. 2D). There were no differences between the DAMGO effects in young and adult rabbits. All DAMGO effects were reversed by local naloxone injection (fig. 2B–D). Local naloxone reversal was obtained in all animals except for the first six adult rabbits where no change in amplitude or RR was observed with DAMGO injection during the experiments. However, off-line analysis revealed changes in inspiratory and expiratory fraction irrespective of changes in RR. Thus, subsequently local naloxone reversal was performed in all animals and completely reversed the effects of DAMGO injection. Since the change in Ti and Te during the initial experiments did not differ from the subsequent experiments where no change in RR was observed, we included these data in our analysis.

**Protocol 2: Effects of Clinical Opioid Concentrations on the preBC in Young and Adult Rabbits**

Fourteen protocols were completed in young rabbits (13 to 23 days, 110 to 550 g). An example is shown in figure 3A. Univariate analysis of the pooled data showed that intravenous remifentanil led to a significant decrease in RR (-18.3 ± 12.3 breaths/min, \( P < 0.001 \)), which was due to a large increase in Te (3.5 [1.1 to 5.7], \( P < 0.05 \)). Ti was not significantly changed (0.6 [−0.1 to 0.8] s, \( P = 0.06 \)), resulting in a decrease in inspiratory fraction from 0.6 (0.5 to 0.7) to 0.4 (0.3 to 0.5) (\( P < 0.05 \)) and a corresponding increase in expiratory fraction from 0.4 (0.3 to 0.5) to 0.6 (0.5 to 0.7) (\( P < 0.05 \)). PPA was significantly decreased (-8 [-6 to -18] a.u., \( P < 0.001 \)) indicating a decrease in respiratory drive (-56% [-39 to -81%], \( P < 0.001 \)). Local injection of naloxone into the preBC led to a partial reversal of the Te/Te ratio with an increase in Ti/Ttot and corresponding decrease in Te/Ttot by 0.18 ± 0.15 (\( P < 0.05 \)). This effect also resulted in a partial reversal (-300 ± 336%, \( P = 0.003 \)) of the increase in normalized Te (+516 ± 434%, \( P < 0.001 \)). All remifentanil effects were completely reversed with intravenous naloxone, that is, they were not different from control.

Sixteen protocols were completed in adult rabbits (3.6 to 5.6 kg). Univariate analysis of the pooled data showed that intravenous remifentanil significantly decreased RR (-10.3 [-7.2 to -13.1] breaths/min, \( P < 0.05 \)) and PPA (-23 [-12 to -36] a.u., \( P < 0.05 \)) and also led to a decrease in respiratory drive (-64% [-40 to -71%], \( P < 0.05 \)). These effects could not be antagonized by local naloxone injection, but they were readily reversed by intravenous naloxone. Intravenous remifentanil did significantly change Ti (0.5 [0 to 0.8] s, \( P = 0.36 \)) but increased Te (3.8 [1.8 to 8.8] s, \( P < 0.05 \)). Remifentanil decreased the inspiratory fraction (-0.27 ± 0.19, \( P < 0.001 \)) and increased the expiratory fraction (0.27 ± 0.19, \( P < 0.001 \)), and this effect was partially reversed by local injection of naloxone into the preBC (0.1 ± 0.1, \( P = 0.01 \)).

The interactions of drug effects and animal age were subsequently analyzed for RR, respiratory drive, and inspiratory fraction using 2-way, repeated measures ANOVA (fig. 3B–D). Local naloxone injection did not change RR (-3 ± 16 breaths/min, \( P = 0.31 \)) or respiratory drive (11 ± 44%, \( P = 0.22 \)), but it significantly reversed the shortening of the inspiratory fraction (0.14 ± 0.14, \( P < 0.001 \)). There were no significant differences in drug effects between adult and young animals. These results suggest that in adult and young rabbits, intravenous remifentanil causes changes in respiratory phase timing through direct action on the preBC. In addition, intravenous remifentanil has significant effects on areas outside the preBC, which ultimately mediate the depression of RR.

**Protocol 3: Potential Endogenous Opioid Effects on the preBC in Young and Adult Rabbits**

In three young and three adult rabbits, we injected naloxone into the preBC at volumes identical to protocols 1 and 2. Localized bilateral injection of naloxone into the preBC did not affect PPA (\( P = 0.262 \)), RR (\( P = 0.07 \)), Ti (\( P = 0.18 \)), Te (\( P = 0.68 \)), or the Ti/Te ratio (\( P = 0.43 \)), neither in the pooled data nor in separate data for young and adult rabbits. This suggests that in decerebrate rabbits, there is no endogenous opioidergic tone in the preBC under the conditions of the experiment.
The model was developed using mean values for $T_i$ and $T_e$ obtained from protocol 2 and is shown in figure 4. In short, the model proposes that under control conditions, input from the preBC prolongs and input from non-preBC sources shortens inspiratory duration, while both preBC and non-preBC inputs shorten expiratory duration. Systemic (intravenous) remifentanil reduces preBC and non-preBC inputs, which causes an increase in inspiratory and expiratory duration with a resulting decrease in RR. Selective local reversal of the remifentanil effect with naloxone in the preBC restores the preBC input to $T_i$ ($F_{i\text{preBC}}$) and to $T_e$ ($F_{e\text{preBC}}$), which leads to an additional increase in inspiratory duration and a decrease in expiratory duration resulting in no change in RR. Additional reversal of the systemic opioid effects on the non-preBC sources with systemic (intravenous) naloxone reduces inspiratory duration and expiratory duration and restores RR to control values.

The pooled results for 16 adult and 14 young rabbits in protocol 2 are shown in table 1. Statistical analysis showed no significant difference in the magnitude of non-preBC and preBC inputs to $T_i$ and $T_e$ between adult and young rabbits. Of note, in adult animals, the non-preBC input to $T_e$ was significantly larger than the preBC input (3.5 [-5.2 to 1.1], $P = 0.04$).

**Discussion**

To our knowledge, this is the first systematic attempt to compare the effects of systemic opioid administration resulting in clinically relevant effect site concentrations and the effects of local microinjection of pharmacological opioid doses on the preBC in young and adult animals of the same species in vivo. The results allow three important conclusions: (1) in young and adult rabbits, clinical opioid concentrations similarly affect inputs to respiratory phase timing that are mediated by the preBC. (2) In young and adult rabbits, systemic opioids also affect inputs to the RR and pattern generator that are derived from outside the preBC. (3) In adult rabbits, non-preBC input to expiratory phase duration is larger than the preBC input.

Extensive in vivo studies performing neuronal recordings with cross-correlation analysis$^{22,28,29}$ and in situ studies performing repeat sectioning of the brainstem$^{30}$ have delineated the Central Pattern Generator as a network of neurons that converts tonic excitatory chemodrive$^{31,32}$ into a respiratory pattern with distinct inspiratory and expiratory phases. The
Central Pattern Generator includes the parabrachial and Kölliker-Fuse nuclei in the pons and the preBC and Bötzinger Complex in the medulla oblongata. Prior studies in neonatal rodent models generally pointed to an important role of the preBC in opioid-induced respiratory depression, while adult in vivo studies found no reversal of the respiratory depression from clinical opioid concentrations in the preBC. However, the latter study did not evaluate for opioid-induced changes in relative phase duration, that is, changes in the Ti/Te ratio. The current study provides evidence that both preBC and non-preBC inputs to the Central Pattern Generator are depressed by systemic opioids at clinical concentrations. However, these inputs—and thus opioid-induced depression of these inputs—have separate and partly opposite effects on inspiratory and expiratory phase duration. Such differential effects were exposed when reversal of the opioid effect on preBC inputs changed the respiratory pattern but did not reverse the depression of RR (fig. 3). An area outside the preBC that mediates opioid effects on respiratory pattern may be located in the pons. In vivo studies in adult cats have described an opioid sensitive area in the pons where morphine injections decreased RR. Recently, an in vivo study in adult dogs demonstrated that injection of naloxone into the parabrachial nucleus reversed RR depression from intravenous remifentanil. Alternatively, Zhang et al. described in an adult in vivo rat preparation that injections of the opioid antagonist CTAP (D-Phe-Cys-Tyr-D-Trp-Arg-Thr-Pen-Thr-NH2) into the caudal medullary raphe partially reversed the decrease in RR. This suggests that respiratory chemoreceptor discharge may not only determine peak phrenic amplitude but also affect on RR. It will be important to establish whether these areas have similar relevance in the developmental rabbit model.

Our hypothetical model showed that non-preBC input to inspiratory phase duration was larger than preBC input in adult but not in young rabbits; however, the age difference was not statistically significant (table 1). In protocol 2, expiratory duration could be partially reversed with naloxone in the preBC in young rabbits (one-way ANOVA), but the difference between young and adult rabbits was not statistically significant (2-way repeated measure ANOVA). Greater importance of non-preBC inputs in adult animals has been postulated as the respiratory pattern changes from a neonatal, pacemaker-driven pattern originating in the preBC to a more mature, network-generated pattern that depends on excitatory drive from the pons. This may also explain divergent results from neonatal rodent studies describing an important role of the preBC in opioid-induced respiratory depression and adult in vivo studies that located the effect in the pons. Our study was underpowered to detect subtle differences between the two age groups; however, it shows the importance of repeat these studies in other areas of the Central Pattern Generator.

Determining the dominant locations of opioid-induced respiratory depression may allow the development of drugs that specifically target the depressed areas and prevent this serious side effect. So far, studies have focused on substances that would stimulate the preBC, for example, Ampakines, D1 agonists, 5HT4A agonists, and 5HT1A agonists though with limited success. Our data suggest that opioid-induced respiratory depression likely cannot be reversed by drug action targeted exclusively at a single area.

Fig. 4. Hypothetical model of preBötzinger Complex (preBC) and non-preBC inputs to inspiratory and expiratory phase duration to explain the observed systemic opioid effects on respiratory phase duration. (A) Intrinsic drive that maintains the inspiratory phase (Ti) is modified by input from the preBC (FpreBC) and by input from outside the preBC (Fnon), resulting in the observed inspiratory duration (Ti). Under control conditions, preBC input increases (+) and non-preBC input shortens (−) inspiratory duration. Intravenous remifentanil reduces both inputs by the factor (1 − r), resulting in an increase in inspiratory duration. Local reversal of the remifentanil effect with naloxone in the preBC restores the preBC input to Ti (FpreBC), which leads to an additional increase in inspiratory duration. Additional reversal of the inhibition of non-preBC input (Fnon) with intravenous naloxone reduces inspiratory duration to baseline. (B) Intrinsic drive that maintains the expiratory phase (Te) is modified by input from the preBC (FpreBC) and by input from outside the preBC (Fnon), resulting in the observed expiratory duration (Te). Under control conditions, both preBC input and non-preBC input shorten (−) expiratory duration. Intravenous remifentanil reduces both inputs by the factor (1 − r), resulting in an increase in expiratory duration. Local reversal of the remifentanil effect with naloxone in the preBC restores the preBC input to Te (FpreBC), which leads to a decrease in expiratory duration. Additional reversal of the inhibition of non-preBC input (Fnon) with intravenous naloxone reduces expiratory duration to baseline.

Computations used the equations outlined in the appendix and were based on the individual data for 16 adult and 14 young rabbits as obtained in protocol 2; results are presented as median (25 to 75%). Data for inspiratory (Ti) and expiratory duration (Te) were analyzed separately. Kruskal–Wallis ANOVA on ranks with Dunn method for multiple comparisons was used to identify differences between inputs derived from outside the preBC (Fnon) and inputs derived from the preBC (FpreBC) in adult and young rabbits. In adult animals, inputs to Te derived from outside the preBC were significantly larger than inputs from the preBC.

Methodological Considerations

Choice of Species and Age. The choice of rabbits allowed conducting identical protocols in young and adult animals of the same species with young animals large enough to allow for our complex instrumentation and differential drug injections. The technical difficulty limited us to using “young” rabbits between 2 and 3 weeks of age. This may explain the less pronounced respiratory depressant effect of opioids on the preBC we observed compared to neonatal rat preparations (≤7 days), as well as the lack of difference between adult and young animals. However, rabbits are born at a rather premature stage. Immaturity of the ventilatory pattern, that is, apnea in response to hypoxia, was observed in rabbits up to 22 days of age in our preparation (unpublished data describing the hypoxic ventilatory response, Astrid Stucke, Associate Professor, M.D., Department of Anesthesiology, Medical College of Wisconsin, Milwaukee, Wisconsin, 2008) and up to 6 weeks by Waites et al.42

Identification of the preBC. We used functional identification of the preBC and also injected DAMGO and naloxone at 1 mm rostral and caudal of the presumed preBC location. Assuming spherical spread, a spread of ~450 μm in all directions would be expected for an injection volume of 70 nl, 540 μm for 140 nl, and 740 μm for 350 nl.43 Injection beyond the borders of the preBC into closely adjacent areas of the ventral respiratory column should not have confounded the results because the area caudal of the preBC does not mediate opioid-induced changes in respiratory pattern44 and injection of endomorphine-1 into the area rostral of the preBC, that is, the Bötzing Complex, affected the respiratory pattern similarly to injections into the preBC.5 DAMGO injection outside this area did not cause any changes in respiratory pattern (unpublished data describing DAMGO injection outside the “tachypneic area,” Astrid Stucke, M.D., Associate Professor, Department of Anesthesiology, Medical College of Wisconsin, Milwaukee, Wisconsin, 2011). Even if RR was unchanged, injections into the preBC changed the respiratory pattern in all animals suggesting that the injections were made in the correct area. Despite a major increase in body weight between 2 weeks and adulthood, brainstem dimensions increase by only ~60%, which made it reasonable to employ the same injection pattern in young and adult animals.

Sufficient Injection Volume. Volumes for DAMGO and naloxone injections were chosen to achieve maximal local effect without affecting chemoreception in adjacent areas.35 The effects of DAMGO injection and subsequent naloxone reversal were generally observed within a minute after each injection suggesting that the effects were truly localized. In those adult animals where DAMGO decreased RR, the effect was achieved with the first injection (140 to 210 nl). In animals without effect on RR, additional DAMGO injection (140 nl) did not change the result.

Statistical Power to Detect Age Differences. The large variability in the effects of DAMGO injection into the preBC in adult rabbits was not present in young rabbits. A power analysis for 2-way repeated measures ANOVA46 suggested that given the large variance approximately 40 young and 40 adult animals would be necessary to establish statistically significant differences, that is, our study was likely underpowered to detect smaller age-dependent differences. The change in RR in adult rabbits ranged between ~81% and +68%. Such variance has also been reported in urethane-anesthetized, spontaneously breathing adult rats where endomorphine-1 injection into the preBC caused changes in RR between ~45% and +45%.45 The changes in adult animals were qualitatively different from the pattern observed in young animals and from the pattern observed with intravenous opioids in young and adult animals.5,9,39

Quantitative Assessment of preBC and Non-preBC Inputs. Table 1 presents an estimate of the magnitude of preBC and non-preBC contributions to the duration of inspiratory and expiratory phase. Inputs were computed using values for the intrinsic timing properties Tiø and Teø derived for r = 0.5. However, the actual depression of RR in protocol 2 varied between animals around the target of 50%. This would have resulted in a range of actual r values and consequently in greater variability of the opioid effects on preBC and non-preBC inputs. The resulting variance in the pooled data likely reduced our ability to identify all but the largest differences. This does not diminish our finding that the non-preBC contribution to expiratory duration was larger than the preBC contribution and that this was specific for adult rabbits.

Anesthesiology 2015; 122:1288-98

Stucke et al.
In conclusion, this is the first study to show that systemic opioids at clinically relevant concentrations affect respiratory phase timing and depress RR by actions on both preBC and non-preBC inputs to the respiratory pattern generator. The magnitude of these effects was similar in young and adult rabbits. Non-preBC inputs to expiratory phase duration were larger than preBC inputs in adult rabbits.

Appendix: Model to Assess preBC Complex and Non-preBC Contributions to Respiratory Phase Timing

Data from protocol 2 provide values for inspiratory (Ti) and expiratory duration (Te), which can be used to assess the relative contributions of the preBötzinger complex (preBC) to phase duration as far as they are affected by opioids.

We assume that during control conditions (Ticon, Tiremi, Tiremin), the remifentanil effect is “0,” during systemic remifentanil infusion (Tiremi), the remifentanil effect is “r,” and during local naloxone injection into the preBC during systemic remifentanil infusion (Tiremi), the remifentanil effect is “r” for non-preBC inputs and “0” for preBC inputs because of the local opioid antagonism.

Inspiratory phase duration (Ti) can be calculated according to

\[ Ti = Ti_\varnothing - F^{\text{non}} \times (1-r) + F^{\text{preBC}} \times (1-r) \]  

For the individual conditions, this yields the following relationships:

\[ T_{i\text{non}} = Ti_\varnothing - F^{\text{non}} \times (1-r) + F^{\text{preBC}} \times (1-r) \]  

\[ T_{i\text{preBC}} = Ti_\varnothing - F^{\text{non}} \times (1-r) + F^{\text{preBC}} \times (1-r) \]  

Using the values for \( Ti_{i\text{non}} \), \( Ti_{i\text{preBC}} \), and \( Ti_{i\text{preBC}} \), we performed repeat computation with various assumed values for Ti\(_\varnothing\) until \( r = 0.5 \), that is, a 50% reduction of all inputs by remifentanil. The \( r \) value was chosen to match the 50% decrease in respiratory rate that was targeted in protocol 2. This yielded values for Fn\(_{\text{non}}\), FpreBC, and F\(_{\text{non}}\) for each individual animal. Pooled data from all animals indicated a negative value for the factor Fn\(_{\text{non}}\) \times (1-r), that is, non-preBC input shortened inspiratory duration (fig. 4A).

Like computations were performed for expiratory phase duration (Te) using individual values for Te resulting from protocol 2. Repeat computation showed that both pontine and medullary inputs shortened Te (fig. 4B).

\[ Ti_{i\text{non}} = Ti_\varnothing - F^{\text{non}} \times (1-r) + F^{\text{preBC}} \times (1-r) \]  

\[ T_{e} = Te_\varnothing - F^{\text{non}} \times (1-r) + F^{\text{preBC}} \times (1-r) \]
