

Alcohol-Folate Interactions in the Risk of Oral Cancer in Women: A Prospective Cohort Study

Jayapriyaa R. Shanmugham^{1,3}, Athanasios I. Zavras^{1,5}, Bernard A. Rosner^{1,4}, and Edward L. Giovannucci^{1,2,4}

Abstract

Background: The aim of this cohort study was to quantify the effect of alcohol on the risk of oral cancer in different strata of folate intake, controlling for known confounders.

Methods: A cohort of 87,621 women in the Nurses' Health Study was followed up from 1980 to 2006, and 147 incident oral cancer cases were reported and confirmed. Data on alcohol intake and diet were obtained through self-reported food frequency questionnaires every 4 years. Cox proportional regression analysis was conducted to estimate the adjusted risk ratios (RR) and 95% confidence intervals (95% CI).

Results: When compared with nondrinkers, the adjusted RRs (95% CIs) for alcohol intake were 0.59 (0.39-0.87) for 0.1-14.9 g/d, 1.15 (0.67-1.97) for 15-29.9 g/d, and 1.92 (1.08-3.40) for ≥ 30 g/d. We observed a significant interaction between alcohol and folate intakes ($P = 0.02$). The cancer risk for subjects with high alcohol (≥ 30 g/d) and low folate (< 350 $\mu\text{g}/\text{d}$) intakes was significantly elevated (RR, 3.36; 95% CI, 1.57-7.20) as compared with nondrinkers with low folate intake. The risk associated with high alcohol intake (≥ 30 g/d) was reduced to 0.98 (0.35-2.70) in the high-folate (≥ 350 $\mu\text{g}/\text{d}$) group as compared with nondrinkers with high folate intake.

Conclusions: High alcohol intake is associated with significantly increased oral cancer risk, especially in women with low folate intake.

Impact: A significant interaction between alcohol and folate intakes seems to affect oral cancer risk in women, a finding with potential public health utility. *Cancer Epidemiol Biomarkers Prev*; 19(10); 2516-24. ©2010 AACR.

Introduction

Oral cancer is a global health problem, with annual estimates of 300,000 new cases globally and 35,000 new cases in the United States (1, 2). The rates vary globally based on the prevalence of risk factors such as tobacco, alcohol, and betel quid use (3). About 90% of the cases are squamous cell carcinomas and the overall 5-year survival rate for oral cancer is ~50% (4). The rates among women are lower when compared with men; however, recent trends show an increase in incidence among women (5). In 1950, the male-to-female ratio was 6:1, but by the year 2002, the gap had closed to a ratio of 2:1. Oral cancer occurs most commonly in adults of ages 40 years and above. Established risk factors for oral cancer are

tobacco use, excessive alcohol intake, betel quid use (a prevalent habit in South and East Asia involving intra-oral use of a mixture of areca nut, lime, and tobacco wrapped in a betel leaf), a diet poor in fruit consumption, and immunosuppression (6).

Excessive alcohol consumption has been consistently associated with risk of cancer, particularly cancers of the liver, digestive tract, and oral cavity (7). In the United States, men who consume 2+ drinks per day and women who consume 1+ drinks per day seem to experience higher incidence of oral cancer (8). The majority of the studies in oral cancer epidemiology involve men, especially smokers. Among nonsmokers, oral and pharyngeal cancers are relatively rare, and few published studies have included enough cases to provide meaningful information about the effect of alcohol especially among women (9). Although several lines of evidence indicate that women may be more susceptible than men to alcohol-induced carcinogenesis (10, 11), the magnitude of the effect of alcohol on the risk of oral cancer in women remains understudied.

Studies in recent years have reported an association between folate deficiency and risk of cancer (12, 13). For example, dietary folate intake has been found to be associated with lower risk of colorectal cancer (14, 15). In oral cancer, only a few case-control studies have considered the possible role of folate, and their results have been inconsistent (16-19). Similarly inconsistent are the analyses

that consider low folate and high alcohol intakes (19), despite the fact that a strong interaction seems to exist in colon cancer, whereby risk is highest in those with high alcohol and low folate intakes (14, 20).

To our knowledge, our study is one of very few prospective studies of oral cancer in women examining the interaction between alcohol and folate in oral cancer risk.

Materials and Methods

Study population: Nurses' Health Study

The study population included women who participated in the Nurses' Health Study I (NHS), an ongoing prospective cohort that was initially established in 1976 (21, 22). Historically, in 1976, a total of 121,701 married registered female nurses from 11 U.S. states, between the ages 30 and 55 years, responded to a baseline questionnaire on lifestyle factors, behaviors, personal characteristics, medical history, and diagnosis of diseases. Since then, follow-up questionnaires have been mailed every 2 years to update information on risk factors and the onset of newly diagnosed diseases. Each follow-up cycle has achieved overall response rates of 90% or higher. This investigation was approved by the Institutional Review Board of the Brigham and Women's Hospital, Boston, MA. Deaths are identified from the post office, next-of-kin, and the National Death Index, with an estimated ascertainment of 98% of all deaths (23). In 1980, the first semiquantitative Food Frequency Questionnaire (FFQ) was mailed to the participants. Follow-up diet questionnaires were mailed in 1984, 1986, and every 4 years thereafter.

Exposure assessment

The baseline FFQ in 1980 included 61 questions on food and food products consumed including dairy products, fruits, vegetables, meats, sweets, baked goods, cereals, and beverages (24). Participants reported detailed information on the frequency of consumption over the past year for each food item using common units or portions. Total nutrient intakes were calculated by multiplying the frequency of consumption by the nutrient content and summing the products over all food items (25). The Harvard University Food Composition Database, which was derived from the U.S. Department of Agriculture database, was used as the source for calculations of nutrient values (26). The use of the semiquantitative FFQ to obtain information on intake of dietary factors has been found to be valid and reliable in the NHS (27, 28). The validity of the FFQ was compared with 1-year diet records and the mean nutrient intake reported in the FFQ was found to be within 10% of the measurements in the diet records. Information on vitamins and mineral supplements was recorded in the FFQs starting in 1980 (29). Both current intake and total years of intake were recorded. For folate, we calculated "total folate," measured in micrograms per day, to be the sum of folate intake from food sources, vitamin supplements, and fortification of foods with folic acid. Assessing total folate through the FFQ has been validated in

the NHS cohort and has been shown to correlate with erythrocyte folate concentrations ($r = 0.55$; ref. 25).

With regard to alcohol, detailed data were first collected in the 1980 FFQ and were updated in all subsequent FFQs. Information on total alcohol intake, type of alcoholic drink (beer, liquor, and wine), and frequency of consumption in the previous year is routinely collected. For purposes of statistical analysis, the alcohol content of each beverage was estimated to be 13.1 g per 12-ounce bottle or can of beer, 11 g per 4-ounce glass of wine, and 14 g per standard drink or shot of liquor (30). Total alcohol intake was calculated as the sum of all alcoholic beverages. Former alcohol drinking was evaluated at baseline based on whether the participants greatly increased or greatly decreased their intake in the previous 10 years and if they were currently nondrinkers. The method of assessing alcohol using a self-administered questionnaire has been shown to be valid and reproducible in the NHS cohort (31). Alcohol consumption reported in the FFQ in 1980 and 1981 was highly correlated with the information assessed by 1-week diet records ($r = 0.90$). Four years later, in 1984, the participants reported alcohol consumption in the previous 4 years, and this was also highly correlated with the weekly diet records ($r = 0.84$).

Outcome assessment: oral cancer

The outcome of our study, oral cancer, was first self-reported in 1976 and was subsequently updated every 2 years thereafter. For our study, self-reports were followed by reviews of the medical and pathology reports and were adjudicated by study physicians who were blinded to risk factor information. The International Classification of Diseases ninth revision (ICD-9) codes 141-146 and 148 were used to categorize the oral cancers according to site or region (Appendix 1; ref. 32). To avoid including cancers with etiologies that are known to be different than that of epithelial cancer, we excluded cancers of the lip and nasopharynx (ICD codes 140, 147, and 149). Following the above exclusions during the follow-up period 1980-2006, a total of 147 confirmed oral cancer cases were included in our analyses.

Data analysis

For each participant, the follow-up period started from the date of return of baseline questionnaire (June 1980) to the date of diagnosis of oral cancer, death, or end of follow-up (December 2006), whichever occurred first. Those who did not complete the diet questionnaire in 1980 and those diagnosed with cancer in 1980 (except for nonmelanoma skin cancer) were excluded, leaving 87,621 participants with complete information to participate in the analyses.

At each follow-up cycle, only those who were free of oral cancer and who were alive were included. Confirmed cases were censored from subsequent follow-up.

Total alcohol intake was categorized as 0, 0.1 to 14.9, 15 to 29.9, and ≥ 30 g/d. Total folate intake ($\mu\text{g}/\text{d}$) was used

Table 1. Baseline characteristics of NHS participants by alcohol intake in 1980 ($n = 87,621$)

*The smoking categories do not add up to the total due to missing values.

as a continuous variable and as a categorical variable. The mean folate value in our cohort was used as the approximate cutoff level for the binary folate variable (<350 versus ≥ 350 $\mu\text{g}/\text{d}$). To evaluate the joint association between alcohol and folate, a combination variable was created for three alcohol levels, 0 to 4.9, 5 to 14.9, and ≥ 15 g/d, across binary folate categories. The cumulative average updating method was used for all of the nutrient variables, including alcohol and folate. The diagnosis of oral cancer was modeled in relation to the cumulative averages from all available dietary questionnaires up to the start of each 2-year follow-up interval. The cumulative average updating method is recommended to estimate long-term intakes and has been found to reduce within-person variations (33). Mechanistically, for the outcome (oral cancer) diagnosed between 1980 and 1984, alcohol data from the 1980 FFQ were used. For outcomes reported between 1984 and 1986, the average of the alcohol data from 1980 and 1984 FFQs was used. For outcomes reported between 1986 and 1990, the aver-

age of the 1980, 1984, and 1986 FFQs was used; and so forth. Once a participant was diagnosed with oral cancer, her alcohol information was not updated starting from the beginning of the time interval in which they were diagnosed.

Multivariate Cox regression analysis with time-varying covariates was performed to calculate hazard ratios and 95% confidence intervals (95% CI) as estimates of relative risk (RR). Linear trends were evaluated by entering a single ordinal variable, and the Wald test for trend was conducted to estimate the *P* value for the test for trend (34). The alcohol-folate interaction was evaluated by entering an interaction term in the multivariate model. Subsequently, the likelihood ratio test was used to compare models with and without the interaction term. Also estimated were the joint-effect estimates for alcohol-folate levels and the stratum-specific estimates for alcohol across folate categories. Multivariate models were adjusted for age (years), follow-up time (2 years), smoking status (current versus past/never), pack-years of smoking (0, 1-19,

20-39, and ≥ 40 pack-years), and total folate intake (< 350 versus ≥ 350 $\mu\text{g}/\text{d}$).

Results

The participants' characteristics at baseline are shown in Table 1. Among the 87,621 participants, 32% reported no alcohol intake in 1980 and 12% reported ≥ 15 g/d of alcohol intake. The overall mean age among the participants at baseline was 47 years. Those who were never smokers were more likely to be nondrinkers or light drinkers. Those who consumed ≥ 30 g/d of alcohol also were more likely to report current cigarette smoking. The mean folate intake in this population was 353 $\mu\text{g}/\text{d}$. Approximately 64% of the participants reported < 350 $\mu\text{g}/\text{d}$ of folate intake across the alcohol intake categories.

As mentioned previously, we identified a total of 147 confirmed cases of oral cancer during the follow-up period 1980-2006. The distribution of cases by level of alcohol intake is shown in Table 2. In the age-adjusted analysis, cumulative average alcohol intake was significantly associated with oral cancer among women who consumed ≥ 30 g/d when compared with those who do not drink (RR, 2.70; 95% CI, 1.57-4.65). Low to moderate alcohol drinking was associated with lower risk (RR, 0.57; 95% CI, 0.39-0.84). In the multivariate model adjusted for age, follow-up time, pack-years of smoking, smoking status, and folate intake, high alcohol intake of ≥ 30 g/d was significantly associated with increased risk (RR, 1.92; 95% CI, 1.08-3.40) compared with nondrinkers. As expected, the risk further increased for subjects who were heavy drinkers and current smokers. We also considered former alcohol drinking, type of alcoholic beverage consumed, fruit intake, multivitamin use, and marital status as possible confounders, but these variables were not signifi-

cantly associated with risk and were later dropped from the analysis. The risk for those who consumed 15 to 29.9 g/d of alcohol was not significantly higher when compared with nondrinkers. In the multivariate analysis, folate intake of ≥ 350 $\mu\text{g}/\text{d}$ was inversely associated with oral cancer risk ($\sim 20\%$); however, the result was not significant (results not shown).

As mentioned earlier, the interaction between alcohol and folate intakes was evaluated by including an interaction term in the multivariate model and evaluating its significance using the Wald statistic. The interaction test was statistically significant, with a P value of 0.02, when controlling for smoking, age, and follow-up time. We also assessed the interaction using the likelihood ratio test comparing the nested model without the interaction with the one that included the interaction term; the likelihood ratio test was found to be significant ($P = 0.02$). The effect of alcohol intake on the risk for oral cancer for each stratum of folate intake (i.e., < 350 and ≥ 350 $\mu\text{g}/\text{d}$) was evaluated, adjusting for pack-years, smoking status, age, and follow-up time (Table 3). Among those with ≥ 350 $\mu\text{g}/\text{d}$ of folate intake, the risk was lower for all categories of alcohol drinking when compared with nondrinkers, although the overall trend was not significant. Among those with low folate intake (< 350 $\mu\text{g}/\text{d}$), high alcohol drinkers (≥ 30 g/d) had significantly higher risk (RR, 3.36; 95% CI, 1.57-7.20) compared with nondrinkers.

Discussion

One of the major findings of this prospective analysis of 87,621 women with 26 years of follow-up was that high alcohol intake (≥ 30 g/d or ~ 2 drinks/d) seems to be significantly associated with increased risk of oral cancer after adjusting for age, tobacco use, folate intake, and

follow-up time. Our results also show a significant interaction between alcohol consumption and folate intake; alcohol seems to increase the risk significantly only for those with low folate intake (<350 µg/d).

The WHO Global Status Report (7) places the RRs for oral cancer among women at 1.45 for those consuming 0 to 19.99 g/d of alcohol, at 1.85 for those consuming 20 to 39.99 g/d of alcohol, and at 5.39 for those consuming 40+ g/d of alcohol. While it is helpful to have such summary estimates, a qualitative assessment of the published literature indicates that studies on the alcohol-oral cancer risk association are mostly case-control studies that involve men, predominantly smokers (3, 11). In men, prospective studies agree with case-control studies in that high levels of alcohol intake lead to higher cancer risk (35, 36). A large multicenter pooled analysis of 15 studies from North America, Europe, and South America showed that, overall, for men and women, the odds ratio (OR) for ≥3 drinks/d versus no drinking was 2.04 (95% CI, 1.29-3.21), with a weak effect of alcohol among never smokers (37). However, specifically among women, the role and extent of alcohol as a risk factor of oral cancer has been inconsistent (37-40), possibly because the studies have been mostly case-control in design and have very few female participants. In a well-controlled large study of 1,114 patients and 1,268 population-based controls, Blot et al. showed that alcohol was an independent risk factor for oral and pharyngeal cancers, with the risk estimates being similar among men and women (38). A case-control study in Italy found that the risk increased among non-smoking women only for those consuming ≥35 drinks per week, a heavy consumption equivalent to 5 drinks per day (39). In this group of heavy drinkers, women experienced higher risk (OR, 14.4; 95% CI, 4.2-92.7) than men (OR, 2.4; 95% CI, 0.5-12.1), but according to the authors, the risk estimates were not statistically heterogeneous. In a similar case-control study of oral cancer in Greece, Zavras et al. confirmed a higher risk of oral cancer for men who were exposed to high amounts of alcohol,

but could not confirm an increased risk with alcohol in women (40). A possible explanation for the gender risk differences was that very few women in Greece consume high quantities of alcohol regularly. Macfarlane et al. carried out a combined analysis of data from three large case-control studies of oral cancer conducted in the United States, Italy, and China. They found that whereas risks associated with tobacco smoking were generally consistent across centers, those for alcohol were not (41). In France, alarmed by the fact that oral cancer incidence among women increases annually, Girod et al. studied the characteristics of 171 women with oral cancer who sought care in a hospital ward. Interestingly, the authors report that 51.5% of the cases did not use tobacco and 65.5% did not drink alcohol. Eighty-two women with cancer reported no tobacco and no alcohol drinking. Of the women who reported alcohol drinking, the majority consumed more than 100 g of alcohol per day (42). Questions remain about the etiology of cancer in this low-risk group and ascertainment bias of the alcohol self-reports cannot be excluded.

More recently (2009), Weikert et al. studied lifetime and baseline alcohol intake within the European Prospective Investigation into Cancer and Nutrition (EPIC), a prospective study of 271,253 participants across Europe. The authors reported a 6-fold elevated risk for women consuming >30 g/d at lifetime as compared with women who consumed 0.1 to 6.0 g/d of alcohol at lifetime. Compared with men, the effect of lifetime alcohol consumption was stronger among women ($P_{\text{interaction}} = 0.045$); for oral cavity cancers, the RR per 10-g increase was 1.09 for men and 1.26 for women (95% CI, 1.07-1.49). This longitudinal study supports a higher predisposition of women to alcohol-related carcinogenesis (43).

Multiple mechanisms are involved in alcohol-induced carcinogenesis and several studies have been conducted in both humans and animals (44). Locally in the oral cavity, the ethanol in alcohol produces epithelial atrophy, which increases the penetration of carcinogens through

§ $P < 0.01$.

the oral mucosa (45). This penetration may occur either due to the elimination of the lipid component of the barrier present in the epithelial layer or due to reorganization of the cell membrane by ethanol, which increases permeability. Ethanol by itself has not been proved to be carcinogenic (46); however, acetaldehyde, the primary metabolic product of ethanol, has been established as carcinogenic in animal experiments and possibly carcinogenic in humans as well (47). Acetaldehyde causes DNA mutations and interferes with DNA synthesis and repair (48). Acetaldehyde can also be produced by oral bacteria, adding to the total circulating salivary acetaldehyde. With regard to the genetics of alcohol metabolism, the production of acetaldehyde from ethanol is facilitated by alcohol dehydrogenase. Acetaldehyde is further converted to acetate by aldehyde dehydrogenase. It is interesting to note that genetic polymorphisms of both alcohol dehydrogenase and aldehyde dehydrogenase are associated with increased risk of head and neck cancers (49).

Our adjusted analysis found that high alcohol intake (≥ 30 g/d) was associated with significantly increased risk for oral cancer as compared with nondrinking (Table 2), a finding consistent with the published literature. We also evaluated the interaction between smoking and alcohol (results not shown) and confirmed that the risk was highest for those with high intakes of both tobacco and alcohol. Again, this result is consistent with prior reports (50) and provides external validity to our results. However, low or moderate alcohol intake (0.1-14.9 g/d) was not associated with an increased risk for oral cancer; rather, it was associated with a decreased risk. The literature on the role of low or moderate consumption in the risk of oral cancer or on a possible threshold effect is inconsistent. Some case-control studies have observed a U-shaped relationship between alcohol consumption and the risk of oral cancer. More specifically, a U-shaped relationship has been reported in 6 of 19 case-control studies; according to these studies, drinking small amounts of alcohol seems to be protective but drinking high amounts seems to be detrimental (11). In other studies, the existence of a U-shaped curve could not be assessed because of using < 4 drinks/d as the lowest category cutoff point. This U-shaped relationship has been observed mostly in men, possibly because of the low samples of women in the highest consumption strata (51). In our study, the apparent U-shaped association with alcohol was observed only among women with high folate intake.

It is currently unclear why alcohol at lower levels may be protective against oral cancer. It is plausible that low levels of alcohol in postmenopausal women are correlated with increased insulin sensitivity and elevated estrogen levels (52). Recently, an analysis of 74,372 female participants of the NIH-AARP cohort showed a protective effect of menopausal hormone therapy. Women who had especially received estrogen-progestin menopausal hormone therapy had a 0.47 times the risk to develop squamous cell carcinoma of the upper aerodigestive tract (protective association; ref. 53). However, this finding needs replication.

Studies conducted thus far on the role of folate in oral or head and neck cancer have been case-control and cross-sectional in design. Whereas low serum folate levels have been observed in head and neck cancer patients before (54, 55), the analytic studies report mixed results (17, 19, 56). Folate was associated with slightly increased risk of oral cavity cancers (OR, 1.3; 95% CI, 0.8-2.2) in a hospital-based case-control study conducted in Uruguay, but the results were not statistically significant (17). A hospital based case-control study from Italy and French-speaking Switzerland that enrolled 749 patients and 1,772 controls (115 were female cases) reported an inverse association with folate intake (OR, 0.53; 95% CI, 0.40-0.69) for the highest tertile of intake (≥ 301 ; ref. 18). In that study, the combined effect of high alcohol intake (≥ 38 drinks/wk) and low folate intake (< 235.9 $\mu\text{g}/\text{d}$) showed a 22-fold increase in risk when compared with those with low alcohol intake (< 14.5 drinks/wk) and high folate intake (> 300.7 $\mu\text{g}/\text{d}$). Whereas the overall direction of the results agrees with our findings, such disproportionately strong effects may be due to higher levels of exposure (much higher alcohol intake and significantly lower folate intake among hospital cases) as compared with our study population of female nurses in the United States. Significantly decreased levels of folate were also observed in a small case-control study of 50 subjects with oral leukoplakia, a clinical condition often associated with dysplasia and oral cancer (57). In contrast, a population-based case-control study of oral cancer in Puerto Rico concluded that oral cancer risk was not related to folate (19). In addition, the authors noted that increased folate intake was associated with decreased oral cancer risk, with an adjusted OR in the highest versus lowest quartile of 0.6 (95% CI, 0.4, 1.0), but this protection was restricted to folate intake from fruits (adjusted OR, 0.4; 95% CI, 0.2-0.6; $P_{\text{trend}} = 0.0001$), and not from other dietary folate sources.

The joint association of alcohol and folate in the risk of major chronic disease has been studied previously in the NHS, and a significant interaction between alcohol and folate intakes has been reported in breast and colon cancers and alcohol-related cancers as a group (25).

The mechanism whereby low folate accentuates the association between alcohol and oral cancer risk is currently unclear. Folate is essential for DNA synthesis and repair and for the methylation of biological substances, including phospholipids, DNA, and neurotransmitters (58). DNA methylation is important in the maintenance of DNA stability and in gene expression. Alcohol interferes with several aspects of normal folate transport and metabolism including dietary folate intake, intestinal absorption, transport to tissues, folate storage in the liver, and urinary excretion (59-61). Human and animal experiments suggest that the acute toxicity of alcohol on folate is primarily related to its influence on folate metabolism in the liver (58). Because the metabolism of acetaldehyde from ethanol also occurs locally in the oral cavity, cleavage of folate can occur in the microenvironment of the oral cavity, deterring the positive effects of folate (62). Thus, by impairing folate status and metabolism, ethanol

may enhance cancer risk both systematically and locally and disrupt the DNA synthesis, repair, and methylation of squamous epithelial oral cells (48).

With regard to gender differences, it is currently unclear if there are differences in the effects of alcohol intake on oral cancer. The present study has enrolled and followed up only women, thus precluding the possibility of any direct comparisons. Most studies have involved men, with women being grossly underrepresented among study participants. It is possible that there may be differences in susceptibility to alcohol-induced carcinogenesis, with women being more susceptible, although the evidence is inconclusive (10, 11). It is also possible that a gender effect may exist in alcohol gastric metabolism, which in turn may affect the bioavailability of acetaldehyde in the oral epithelial tissue. In men, the blood level of alcohol is higher when given intravenously as compared with drinking (63). However, women have been found to have similar blood levels of alcohol irrespective of whether the alcohol was given orally or intravenously. This gender difference could be due to lower gastric metabolism of ethanol when compared with men (10, 11). Studies on cancer of the liver have shown that, when compared with men, liver damage is higher among women with lower and shorter-duration intake of alcohol. Hormonal differences in men and women can also play a role in the joint effect of folate and alcohol and how they influence differences in oral cancer risk (52).

Although we were able to assess the main question of interest, the effect of alcohol consumption on oral cancer risk stratifying for levels of folate intake, there are power limitations in studying interactions with other covariates due to low number of cases in some strata. Despite the various ways that the analysis controlled for smoking, residual confounding (by smoking) is always possible, especially among the low folate intake group. As with all epidemiologic studies using a self-administered diet questionnaire, the possibility of measurement error cannot be completely eliminated. However, in our study, we minimized the bias from measurement error by using cumulative averages of repeated measurements over a long follow-up (28, 29, 31). Further, the main exposure of interest, alcohol intake measurements as reported in the FFQ, has been studied extensively and has been validated in the past (31). Misclassification, if any, will be non-differential, thus leading to underestimation of the true association. The potential for misclassification of oral cancer is very minimal because the cancer diagnosis was confirmed by blinded study physicians. With regard to how representative the study subjects are of the U.S. population of women, there are some concerns with regard to generalizability, as the participants are predominantly White. Whereas the range of risk factors could be slightly different from U.S. women in general, we expect the biological relations to be similar. Strengths of our study include a large prospective cohort study design and a follow-up of 26 years with updated information on several time-varying confounders. The NHS cohort included married registered nurses at baseline. Therefore, the cohort is

homogeneous with regard to socioeconomic status, level of education, and health awareness, reducing possible confounding by these factors. Misclassification of alcohol and nutrients is minimal in our study because we used questionnaires that have been found to be valid and reliable (31). Additionally, the NHS cohort includes a group of health professionals that are dedicated to health sciences (by means of consistent volunteering in the Study for over 26 years), and thus we assume that there will be a good degree of accuracy in reporting health information.

In conclusion, alcohol intake of >2 drinks per day leads to a 2-fold increase in the risk of oral cancer in women compared with nondrinkers. This risk increases further in drinkers with low intake of folate. Women with high folate intake have lower alcohol-related risk for oral cancer. Along with discontinuation of tobacco use, public health recommendations to reduce the incidence of oral cancer in women must include minimizing alcohol consumption to a level of 0 to 1 drinks per day and increasing folate intake.

Appendix 1. Classification of diagnostic codes for oral cancer by site/region according to the International Classification of Diseases, ninth revision (ICD-9)

ICD-9 codes	Definition
140	Malignant neoplasm of lip
141	Malignant neoplasm of tongue
142	Malignant neoplasm of major salivary glands
143	Malignant neoplasm of gum
144	Malignant neoplasm of floor of mouth
145	Malignant neoplasm of other and unspecified parts of mouth
146	Malignant neoplasm of oropharynx
147	Malignant neoplasm of nasopharynx
148	Malignant neoplasm of hypopharynx
149	Malignant neoplasm of other and ill-defined sites within the lip

Disclosure of Potential Conflicts of Interest

No potential conflicts of interest were disclosed.
