In this article we look at the motivation for order-sorted term rewriting by considering some of the very natural equational theories in which single-sorted (unsorted) and many-sorted rewriting lack sufficient expressiveness, for various reasons. However, order-sorted rewriting is not without problems of its own, and we consider some of these along with a brief description in each case of some current approaches to their solution.

Received August 1990

1. UNSORTED OR SINGLE-SORTED REWRITING

We assume some familiarity with the general idea of term rewriting, and in particular with the Knuth–Bendix completion algorithm, as found in, for example, Refs 1 or 2. A brief summary follows.

We assume that we have a set of equations $E$, whose terms are composed of constants, variables, and function symbols, all of which are defined in our signature. Let $V$ be our set of variables and $T$ our set of terms. A ground term is one which contains no variables.

In unsorted term rewriting, all constants and variables are considered to belong to some set $S$ and a function symbol $f$ of arity $n$ is defined:

$$f : S^n \rightarrow S$$

We orient each equation into a rewrite rule in accordance with some ordering $\prec$ on terms. Each rule has a left hand side, $l$, and a right hand side, $r$, chosen so that $l \succ r$. Then we write the rule:

$$l \Rightarrow r$$

These rules may now be used in two ways. A rule may reduce a term in another rule or equation if some term $t$ in that rule or equation is matched by $l$, i.e. there exists a substitution

$$\sigma : V \rightarrow T$$

such that $\sigma$ is defined on every variable in $l$, and

$$\sigma l = t$$

Then we replace $t$ by $\sigma r$ at the position $p$ where $t$ occurred in the rule or equation. Suppose $t$ is a subterm of $s$ in the equation

$$s = u$$

Then we write

$$s' = s[p \leftarrow \sigma r] = \sigma u$$

We will try to choose a well-founded ordering so that no term can be reduced infinitely often. For a review of termination orderings see Ref. 3.

A term which cannot be reduced by any rule is said to be in normal form.

The other use we make of rules is in generating new equations which we add to $E$. Consider the case where there exist rules

$$l_1 \rightarrow r_1$$

and

$$l_2 \rightarrow r_2$$

and a term $t$ which can be reduced by the first rule at position $p_1$ and by the second rule at position top. Then $t$ rewrites to both

$$t_1 = t[p_1 \leftarrow \sigma_1 r_1]$$

and

$$t_2 = \sigma_2 r_2$$

for some substitutions $\sigma_1$, $\sigma_2$. Since the rules are really equations, we deduce that $t_1 \equiv t_2$. We say $t_1$ and $t_2$ form a critical pair. If $t_1$ and $t_2$ can be reduced to the same normal form by the rules they form a convergent critical pair. Otherwise $t_1$ is added to $E$ as a new equation.

When all critical pairs are convergent and every equation has been ordered into a rule we say the set of rules is confluent.

For many sets of equations, no confluent set of rules can be found. This can be due to the confluent set being infinite, or it can be because some equation cannot be oriented.

The process of finding critical pairs involves unification, which we do not discuss further here – see Ref. 1 for an introduction to this highly complex area.

1.1 Problems of unsorted term rewriting

There are many natural sets of equations which unsorted term rewriting cannot handle satisfactorily. The most commonly seen example is that of a stack, the signature of which follows.

emp : $\rightarrow S$ (emp is a constant, representing the empty stack)

$V = \{x, x_1, x_2, \ldots, y, y_1, y_2, \ldots\}$

($V$ is the set of variables)

push : $S \times S \rightarrow S$

pop : $S \rightarrow S$ (The three usual functions on stacks)

top : $S \rightarrow D$

The equations are:

pop(push(x, y)) = y

top(push(x, y)) = x

there are two equations in $E$
ORDER-SORTED TERM Rewriting

Now already we have a problem. If we attempt to apply top or pop to the empty stack, we should get an error. So we introduce the additional function symbol error and additional equations as follows:

\[
\begin{align*}
\text{error} & : \to \# \\
\text{pop(emp)} & = \text{error} \\
\text{top(emp)} & = \text{error} \\
\text{push}(x, \text{error}) & = \text{error} \\
\text{top(error)} & = \text{error} \\
\text{pop(error)} & = \text{error}
\end{align*}
\]

This does not yet solve our problem. Consider the term

\[
\text{top(push(x, error))}
\]

This rewrites to both \(x\) and error, so we have the critical pair

\[
x = \text{error}
\]

which is not what we intended.

The problem arises because error is qualitatively different from all other terms, just as stacks and stack elements are qualitatively different. This leads to the idea of many-sorted term rewriting.

2. MANY-SORTED TERM Rewriting

The problems we faced in the example above were caused by our attempting to apply functions to constants to which they should not be applied, in other words generating errors.

We solve these problems by defining every function to have a domain, which includes one or more sorts, and never applying the function outside this domain. Each sort will have its own set of variables, and we restrict substitutions so that any variable can only be substituted by a term of the same sort. Let \(S\) be our (finite) set of sorts.

Then the example of stacks can be expressed as follows:

\[
S = \{\text{STACK, NSTACK, E}\}
\]

(representing the three sorts of stacks, elements and non-empty stacks, respectively)

\[
\begin{align*}
V_\text{E} & = \{e, e1, e2, \ldots\} \\
V_\text{STACK} & = \{y, y1, y2, \ldots\} \\
V_\text{NSTACK} & = \{z, z1, z2, \ldots\}
\end{align*}
\]

(representing the (disjoint) sets of variables for the three sorts)

\[
\begin{align*}
\text{emp} & : \to \text{STACK} \\
\text{pop} & : \text{NSTACK} \to \text{STACK} \\
\text{top} & : \text{NSTACK} \to \text{E} \\
\text{push} & : E \times \text{STACK} \to \text{NSTACK} \\
\text{pop(push(e, y))} & = y \\
\text{top(push(e, y))} & = e
\end{align*}
\]

We have introduced the sort NSTACK to avoid the possibility of applying top or pop to emp, which would lead to the same problems as in the unsorted case. However, now we cannot push elements onto a non-empty stack. For example, \(\text{push}(e1, \text{push}(e2, y))\) is ill-sorted because \(\text{push}(e2, y)\) is of sort NSTACK, which lies outside the domain of push. Clearly we need a further refinement, in order to make terms of sort NSTACK be of sort STACK as well. Thus we arrive at an order-sorted signature.

3. ORDER-SORTED TERM Rewriting

Sorts are defined as before, except that now we specify a partial order \(>\) between sorts (not to be confused with the term ordering \(>\)). If \(A\) and \(B\) are sorts and \(A > B\), we say that \(B\) is a subsort of \(A\). The reflexive closure of \(>\) is denoted \(\geq\). We denote \(A > B\) diagrammatically by:

\[
\begin{align*}
& A \\
\mid & B
\end{align*}
\]

If \(B\) is a subsort of \(A\), then every variable or constant of sort \(B\) is also a variable or constant of sort \(A\). If a function \(f\) is defined on domain \(A\), then \(f\) is defined on \(B\) and \(f(b) = f(a)\), where \(b\) is a term of sort \(B\) and \(a\) is that term regarded as a term of sort \(A\). This extends easily to the case where \(f\) takes more than one argument.

We make the further requirement that substitutions are sort-preserving, i.e. if \(v\) is a variable of sort \(A\), \(t\) must be a term of some sort \(B \leq A\) if \(t\) is to be substituted for \(v\).

We mention in passing that whereas two terms in the unsorted and many-sorted cases can be unified in at most one way, terms in the order-sorted case can be unified in infinitely many ways. The reader is referred to Ref. 4 for details.

Now we can specify operations on stacks as follows.

\[
S = \{\text{STACK, NSTACK, E}\}
\]

(NSTACK is a subsort of STACK)

\[
\begin{align*}
V_\text{E} & = \{e, e1, e2, \ldots\} \\
V_\text{STACK} & = \{y, y1, y2, \ldots\} \\
V_\text{NSTACK} & = \{z, z1, z2, \ldots\}
\end{align*}
\]

\[
\begin{align*}
\text{emp} & : \to \text{STACK} \\
\text{pop} & : \text{NSTACK} \to \text{STACK} \\
\text{top} & : \text{NSTACK} \to \text{E} \\
\text{push} & : E \times \text{STACK} \to \text{NSTACK}
\end{align*}
\]

\[
\begin{align*}
\text{pop(push(e, y))} & = y \\
\text{top(push(e, y))} & = e
\end{align*}
\]

It seems as though everything is in order, as \(z\) is a variable of a subsort of STACK, so it is also a variable of STACK.

However, we still cannot write

\[
\text{pop(pop(push(e1, push(e2, emp)))}
\]

for example. One solution to this is to introduce a top or universal sort \(U\), with the intention that \(A < U\) for every other sort \(A\), and every function \(f\) is defined on \(U\). This has the result that even semantically meaningless terms become syntactically well-sorted, which is obviously
undesirable. Since the solution which we will propose to
the problem of sort-decreasingness (see later) also solves
the above problem, but without defining functions on the
universal sort, we do not pursue the idea of the universal
sort here.

4. PROBLEMS OF ORDER-SORTED
REWITING

We now consider some of the problems of order-sorted
rewriting, and some current approaches to their solutions.
In general, these problems arise because of the
considerable difference between the syntactic world of
term rewriting and the semantic world of the underlying
algebra, so we begin by defining the initial or $\Sigma$-algebra
of an order-sorted term rewriting system. In this section
we follow Ref. 6.

Definition

Let $\Sigma$ be an order-sorted signature, with sorts $S$. Let $E$ be
our set of equations. Then the initial algebra $A$ consists of
denotations $\xi^A$ and $f^A$ for the sort and function
symbols of $\Sigma$, respectively. Let

$$\xi^A = \{ t \mid s = t \text{ is provable in } E \text{ and } t \text{ is a ground } \Sigma\text{-term} \}$$

Then $\xi^A = \{ \xi \mid \xi \text{ is a ground } \Sigma\text{-term of sort } \xi \}$. $C_A = \bigcup (\xi^A \mid \xi \in S)$ is called the carrier of $A$.

$f^A$ is a mapping $D^A_i \to C_A$ whose domain $D^A_i$ is a subset of
$C^\#_i$, where $|f|$ is the arity of $f$.

If $f: \xi_1 \times \ldots \times \xi_n \to \xi \in \Sigma$ and $a_i \in \xi_i$ for $i = 1, \ldots, n$

Then $(a_1, \ldots, a_n) \in D^A_i$ and $f^A(a_1, \ldots, a_n) \in \xi^A$

Further, $f^A(a_1, \ldots, a_n) = f(a_1, \ldots, a_n)$
if $a_1, \ldots, a_n$ are all ground terms.

We are particularly interested in initial algebras
because they have:

no junk

for every $t \in \xi$ there is exactly one $t$ in $\xi^A$

no confusion

$t = s$ in $A$ iff $t = s$ is deducible from $E$.

4.1 Regularity

The first problem we find with our syntax for order-
sorted rewriting is that it allows multiple function
declarations while in the algebra every mapping has only
one denotation. This results in problems such as the following example.

$$S = \{ S_1, S_2, S_3 \}$$

$S_1 \succ S_2$

$S_2 \succ S_3$

$f: S_1 \to S_1$

$f: S_2 \to S_3$

$a: \to S_3$

What is the sort of $f(a)$? $f(a)$ belongs to both $S_1$ and
$S_3$ and to no lower sort. We have to conclude that $f(a)$
has no least sort.

Definition

A signature $\Sigma$ is regular iff the sort order $\succ$ is a
partial order and every $\Sigma$-term $t$ has a unique least sort
LS($t$) such that:

(i) if $t$ is a $\Sigma$-term, $t$ is a term of sort LS($t$)

(ii) if $t$ is a $\Sigma$-term of sort $\xi$, LS($s$) $\leq_\xi \xi$.

Note that the least sort of a term $t$ can be found
effectively as it only depends on the domains and ranges of
functions and the least sort of subterms of $t$.

In particular, in the example above we might define

$$f: S_1 \to S_3$$

to make the signature regular.

In order-sorted term rewriting we are only concerned
with regular signatures, for the practical reason that
unification in regular signatures is finitary, while in non-
regular signatures it is infinitary (in general).

4.2 Void sorts

If a sort is void, i.e. contains no ground terms, we very
quickly run into problems, as the following example from Ref. 7 shows.

The signature is:

$$S = \{ \text{VOID, BOOL} \}$$

$$\text{TRUE} \to \text{BOOL}$$

$$\text{FALSE} \to \text{BOOL}$$

$$V_{\text{VOID}} = \{ x, x_1, x_2, \ldots \}$$

Let the rewrite rules be:

$$f(x) = \text{TRUE}$$

$$f(x) = \text{FALSE}$$

Because $f(x)$ rewrites to both TRUE and FALSE, we can immediately deduce that TRUE = FALSE. However,
this is not true in the initial algebra because $f(x)$ has no
ground instantiation.

We shall adopt the simplest solution to this problem;
we forbid void sorts. An alternative solution is given in
Ref. 7.

4.3 Sort-preserving rewriting

A more serious problem is that order-sorted rewriting is
not complete in the order-sorted case. Consider the following example from Ref. 6.

Signature:

$$S = \{ A, B \} \text{ with } B \succ A$$

$$a: \to A$$

$$a': \to A$$

$$b: \to B$$

$$f: A \to A$$

Rules:

$$a \Rightarrow b$$

$$a' \Rightarrow b$$
In the initial algebra \( \bar{a} = \bar{b} = \bar{a} \).

Therefore
\[
\bar{f}(a) = \bar{f}(a')
\]

must also hold.

However, we cannot deduce that \( f(a) = f(a') \) by rewriting because the term \( f(b) \) is ill-sorted. The problem is that \( \Rightarrow \) does not preserve monotonicity. Namely, \( t \Rightarrow t' \) does not imply \( f(t) \Rightarrow f(t') \) unless

\[
LS(t) \supseteq LS(t')
\]

Until recently, this restriction on term rewriting was accepted, and only signatures in which every rule \( \Rightarrow \) was sort-decreasing, i.e. \( LS(t) \supseteq LS(r), \) were considered. Recently, however, a number of groups have been working independently on this problem, including Gallier & Isakowitz, Watson & Dick, Ganzinger, and Duporcheel.

Again the problem is caused by the difference between syntax and semantics. We have already introduced the syntactic measure of the least sort of a term \( t, LS(t), \) but in fact every term also has a semantic sort. In the initial algebra we define \( t \) for every ground \( \Sigma \)-term \( t \) because we want to do substitution of equals for equals – thus \( t \) is properly regarded as a congruence class. In order to substitute equals for equals within this congruence class, the terms which belong to this class must in some sense have the same sort, in order that a congruence class lies either entirely inside or entirely outside the domain of any given function.

So we define the semantic sort of \( t, S_{\text{SEM}}(t), \) to be

\[
\cap \{ LS(s) \mid s = t \text{ in } \alpha' \}
\]

Now of course \( t = t, \) so we see that \( S_{\text{SEM}}(t) \subseteq LS(t), \) for every \( t. \) Thus our notation becomes inappropriate, and we shall rename the syntactic (least) sort of \( t \) to be \( S_{\text{SYN}}(t). \)

4.3.1 Dynamic sorts

To avoid the restrictions of sort-decreasing rewrite rules we would much rather use the semantic sort \( S_{\text{SEM}} \) in rewriting. Then, rewriting a term never causes it to become ill-sorted. Unfortunately this is not possible, as the semantic sort of a term cannot be found effectively, in general. This is easily seen because for any \( t, i \) may represent infinitely many terms.

The idea of Ref. 10 is to approximate the semantic sort of a term using dynamic sorting. At stage \( s+1 \) in the Knuth–Bendix algorithm, after generating more equations by the critical pairs procedure, we calculate the dynamic sort of each term which occurs in the rules and equations, defined to be

\[
S^{(s+1)}_{\text{DYN}}(t) = \cap \{ S^{(s)}_{\text{DYN}}(t') \mid t = t' \text{ in } E' \}
\]

where \( E' \) is the set of all rules generated up to stage \( s, \)

\[
S^{(s)}_{\text{DYN}}(t) = S_{\text{SYN}}(t)\text{ for every } t.
\]

Note that \( S^{(s+1)}_{\text{DYN}} \subseteq S^{(s)}_{\text{DYN}}(t) \) for every term \( t, \) stage \( s. \)

Now by the completeness of a fair Knuth–Bendix procedure which does not fail,

\[
\lim_{s \to \infty} S^{(s)}_{\text{DYN}}(t) = S_{\text{SEM}}(t)
\]

The use of dynamic sorts ensures that at no stage do we rewrite a term to an ill-sorted term. The use of dynamic sorts also has consequences for unification, proof by contradiction and other facets of term-rewriting, the details of which are covered in Ref. 10, where a formalism (with inference rules) is given in the style of Ref. 13.

The method developed independently by Gallier & Isakowitz is based on the same idea, except that they do not explicitly change the sort of a term during rewriting, but rather allow rewriting to (s syntactically) ill-sorted terms, which they justify with a rigorous proof.

This method is fast and brutal compared to ours; the normal form of a term may be ill-sorted, for instance, and no new information about the semantic sort of a term is produced during the completion procedure. On the other hand their method is obviously much easier to implement, and quicker than the method of dynamic sorts.

Both methods remove the requirement that order-sorted rewrite rules must be sort-preserving.

5. CONCLUSION

We have attempted to introduce the essential aspects of order-sorted term rewriting in a well-motivated semi-formal fashion. We have highlighted some of the particular problems such an approach creates, and discussed possible solutions. The reader is referred to Ref. 6 for a thorough grounding in order-sorted rewriting.
