ABSTRACT

We use a complete sample of about 140 000 galaxies from the Sloan Digital Sky Survey (SDSS) to study the size distribution of galaxies and its dependence on their luminosity, stellar mass and morphological type. The large SDSS data base provides statistics of unprecedented accuracy. For each type of galaxy, the size distribution at given luminosity (or stellar mass) is well described by a log-normal function, characterized by its median $\bar{R}$ and dispersion $\sigma_{\ln R}$. For late-type galaxies, there is a characteristic luminosity at $M_{r,0} \sim -20.5$ (assuming $h = 0.7$) corresponding to a stellar mass $M_0 \sim 10^{10.6}$ $M_\odot$. Galaxies more massive than $M_0$ have $\bar{R} \propto M_0^{0.4}$ and $\sigma_{\ln R} \sim 0.3$, while less massive galaxies have $\bar{R} \propto M_0^{0.15}$ and $\sigma_{\ln R} \sim 0.5$. For early-type galaxies, the $\bar{R} - M$ relation is significantly steeper, $\bar{R} \propto M^{0.55}$, but the $\sigma_{\ln R} - M$ relation is similar to that of bright late-type galaxies. Faint red galaxies have sizes quite independent of their luminosities. We use simple theoretical models to interpret these results. The observed $\bar{R} - M$ relation for late-type galaxies can be explained if the fraction of baryons that form stars is as predicted by the standard feedback model. Fitting the observed $\sigma_{\ln R} - M$ relation requires in addition that the bulge/disc mass ratio be larger in haloes of lower angular momentum and that the bulge material transfers part of its angular momentum to the disc. This can be achieved if bulge formation occurs so as to maintain a marginally stable disc. For early-type galaxies, the observed $\sigma_{\ln R} - M$ relation is inconsistent with formation through single major mergers of present-day discs. It is consistent with formation through repeated mergers, if the progenitors have properties similar to those of faint ellipticals or Lyman break galaxies and merge from relatively strongly bound orbits.

Key words: galaxies: formation – galaxies: fundamental parameters – galaxies: statistics – galaxies: structure.

1 INTRODUCTION

Luminosity, size, circular velocity (or velocity dispersion) and morphological type are the most basic properties of a galaxy. Observed galaxies cover large ranges in these properties, with luminosities between $\sim 10^8$ $L_\odot$ and $\sim 10^{12}$ $L_\odot$, effective radii between $\sim 0.1$ kpc and $\sim 10$ kpc, circular velocity (or velocity dispersion) between $\sim 30$ km s$^{-1}$ and $\sim 300$ km s$^{-1}$, and morphologies changing from pure disc systems to pure ellipsoidal systems. Clearly, the study of the distribution of galaxies with respect to these properties and the correlation among them are crucial to our understanding of the formation and evolution of the galaxy population.

*E-mail: shen@mpa-garching.mpg.de

There has been much recent progress in this area. For example, the luminosity function of galaxies has been measured from various redshift surveys of galaxies and is found to be well described by the Schechter function (Schmidt 1968; Loveday et al. 1992; Lin et al. 1996; Folkes et al. 1999; Madgwick et al. 2002), the morphological type of galaxies is found to be correlated with their local environment (as reflected in the morphology–density relation; Dressler 1980; Dressler et al. 1997) and other properties (e.g. Roberts & Haynes 1994); and galaxy sizes are correlated with luminosity and morphological type (Kormendy 1977), and have a distribution that may be described by a log-normal function (Choloniewski 1985; Syer, Mao & Mo 1999; de Jong & Lacey 2000).

Clearly, in order to examine these properties in detail, one needs large samples of galaxies with redshift measurements and accurate photometry. The Sloan Digital Sky Survey (SDSS, York et al. 2000),
with its high-quality spectra and good photometry in five bands for
\$\sim 10^6$ galaxies, is providing an unprecedented data base for such
studies. The survey is ongoing, but the existing data are providing
many interesting results about the distribution of galaxies with re-
spect to their intrinsic properties. The luminosity function has been
derived by Blanton et al. (2001, 2003c) and the dependence of lumi-
nosity function on galaxy type has been analysed by Nakamura et al.
(2003). Shimasaku et al. (2001), Strateva et al. (2001) and Naka-
mura et al. (2003) have examined the correlation between galaxy morphological type and other photometric properties, such as colour
and image concentration. The Fundamental Plane and some other
scaling relations of early-type galaxies have been investigated by
Bernardi et al. (2003a,b,c). Based on a similar data set, Sheth et al.
(2003) have studied the distribution of galaxies with respect to cen-
tral velocity dispersion of galaxies. By modelling galaxy spectra in
detail, Kauffmann et al. (2003a) have measured stellar masses for a sample of more than $10^5$ galaxies, and have analysed the cor-
relation between stellar mass, stellar age and structural properties
determined from the photometry (Kauffmann et al. 2003b). Blan-
ton et al. (2003b) examined how various photometric properties of
galaxies correlate with each other and with environment density.

In this paper, we study in detail the size distribution of galaxies
and its dependence on galaxy luminosity, stellar mass and mor-
phological type. Our purpose is two-fold: (1) to quantify these properties
so that they can be used to constrain theoretical models; and (2) to
use simple models based on current theory of galaxy formation to
interpret the observations. Some parts of our analysis overlap that
of Blanton et al. (2003b), Kauffmann et al. (2003b) and Bernardi et al.
(2003b), but in addition we address other issues. We pay consid-
erable attention to effects caused by the sample surface brightness
limit and by seeing, we provide detailed fits to the data to quantify
the dependence of the size distribution on other galaxy properties,
and we discuss how these results can be modelled within the current
theory of galaxy formation.

Our paper is organized as follows. In Section 2, we describe
the data to be used. In Section 3, we derive the size distribution
of galaxies as a function of luminosity, stellar mass and type. In
Section 4, we build simple theoretical models to understand the
observational results we obtain. Finally, in Section 4, we summarize
our main results and discuss them further.

2 THE DATA

In this section, we describe briefly the SDSS data used in this pa-
per. These data are of two types: the basic SDSS photometric and
spectroscopic data, and some quantities derived by our SDSS col-
aborators from the basic SDSS data base.

2.1 The basic SDSS data

The SDSS observes galaxies in five photometric bands ($u, g, r,
i, z$) centred at $(3540, 4770, 6230, 7630, 9130 \text{ Å})$ down to (22.0, 22.2, 22.2, 21.3, 20.5 mag), respectively. The imaging camera is
described by Gunn et al. (1998); the filter system is roughly as de-
scribed in Fukugita et al. (1996); the photometric calibration of the
SDSS imaging data is described in Hogg et al. (2001) and Smith
et al. (2002); and the accuracy of astrometric calibration is described
in Pier et al. (2003). The basic SDSS photometric data base is then
obtained from an automatic software pipeline called PHOTO (see
Lupton et al. 2001, 2002), whereas the basic spectroscopic param-
eters of each galaxy, e.g. redshift and spectral type, are obtained by
the spectroscopic pipelines IDLSPEC2D (written by D. Schlegel and S.
Burles) and SPECTRO1D (written by M. SubbaRao, M. Bernardi and
J. Frieman). Many of the survey properties are described in detail
in the Early Data Release paper (Stoughton et al. 2002, hereafter
EDR).

PHOTO uses a modified form of the Petrosian (1976) system for
galaxy photometry, which is designed to measure a constant fraction
of the total light independent of the surface brightness limit. The
Petrosian radius $r_P$ is defined to be the radius where the local surface
brightness averaged in an annulus equals 20 per cent of the mean
surface brightness interior to this annulus, i.e.

$$\int_{0}^{1.25 r_P} \frac{dr 2\pi r I(r)}{\int_{0}^{r} 2\pi r I(r)} = 0.2,$$

(1)

where $I(r)$ is the azimuthally averaged surface brightness profile.
The Petrosian flux $F_P$ is then defined as the total flux within a radius
of $2r_P$,

$$F_P = \int_{0}^{2 r_P} 2\pi r dr I(r).$$

(2)

With this definition, the Petrosian flux (magnitude) is about 98 per
cent of the total flux for an exponential profile and about 80 per cent
for a de Vaucouleurs profile. The other two Petrosian radii listed in
the PHOTO output, $R_{90}$ and $R_{50}$, are the radii enclosing 50 and 90
per cent of the Petrosian flux, respectively. The concentration index
c, defined as $c = R_{90}/R_{50}$, is found to be correlated with galaxy
morphological type (Shimasaku et al. 2001; Strateva et al. 2001;
Nakamura et al. 2003). An elliptical galaxy with a de Vaucouleurs
profile has $c \sim 3.3$, while an exponential disc has $c \sim 2.3$. Note
that these PHOTO quantities are not corrected for the effects of the
point spread function (PSF) and, therefore, for small galaxies under
bad seeing conditions, the Petrosian flux is close to the fraction
measured within a typical PSF, about 95 per cent for the SDSS
(Blanton et al. 2001). In such cases, the sizes of compact galaxies are
overestimated, while their concentration indices are underestimated
by the uncorrected PHOTO quantities (Blanton et al. 2003b).

The SDSS spectroscopic survey aims to obtain a galaxy sam-
ple complete to $r \sim 17.77$ in the $r$-band (Petrosian) magnitude
and to an average $r$-band surface brightness (within $R_{50}$) $\mu_{50} \sim
24.5 \text{ mag arcsec}^{-2}$. This sample is denoted the Main Galaxy
Sample, to distinguish it from another colour-selected galaxy sample,
the Luminous Red Galaxies (LRGs), which extends to $r \sim 19.5$
(Eisenstein et al. 2001). These target selections are carried out by
the software pipeline TARGET; details about the target selection crite-
ria for the Main Galaxy Sample are described in Strauss et al. (2002).
The tiling algorithm of the fibres to these spectroscopic targets is
described in Blanton et al. (2003).

The spectroscopic pipelines, IDLSPEC2D and SPECTRO1D, are de-
designed to produce fully calibrated one-dimensional spectra, to
measure a variety of spectral features, to classify objects by their spectral
types, and to determine redshifts. The SDSS spectroscopic pipelines
have an overall performance such that the correct classifications and
redshifts are found for 99.7 per cent of galaxies in the Main Galaxy
Sample (Strauss et al. 2002). The errors in the measured redshift are
typically less than $\sim 10^{-4}$.

2.2 Derived quantities for SDSS galaxies

In the SDSS PHOTO output, the observed surface brightness profiles
of galaxies are given in PROFIAMEAN where angle-averaged surface
brightnesses in a series of annuli are listed (see EDR), Blanton
et al. (2003b) fitted the angle-averaged profiles with the Sérsic (1968) model,

$$I(r) = I_0 \exp\left(-\frac{(r/r_0)^{1/n}}{1+n}\right).$$  \hspace{1cm} (3)

convolved with the PSF, to obtain the central surface brightness $I_0$, the scale radius $r_0$, and the profile index $n$ for each galaxy. As found by many authors (e.g. Trujillo, Graham & Caon 2001, and references therein), the profile index $n$ is correlated with the morphological type, with late-type spiral galaxies (whose surface brightness profiles can be approximated by an exponential function) having $n \sim 1$, and early-type elliptical galaxies (whose surface brightness profiles can be approximated by the $r^{1/4}$ function) having $n \sim 4$. From the fitting results, one can obtain the total Sérsic magnitude $I_n$, the Sérsic half-light radius $R_{S0.5}$ and other photometric quantities. In our fitting analysis, we will use these quantities and compare the results so obtained with those based on the original photometric quantities. For clarity, we denote all the Sérsic quantities by a subscript ‘$S$’. We present results for both Petrosian and Sérsic quantities, because, while the Sérsic quantities are corrected for seeing effect, the Petrosian quantities are the standard photometric quantities adopted by the SDSS community.

Recently, Kauffmann et al. (2003a) developed a method to estimate the stellar mass of a galaxy based on its spectral features, and obtained the stellar masses for a sample of 122 808 SDSS galaxies. The 95 per cent confidence range for the mass estimate of a typical galaxy is $\pm 40$ per cent. Below we use these results to quantify size distributions as a function of stellar mass as well as a function of luminosity.

2.3 Our sample

The Main Galaxy Sample we use in this paper is a subsample of the spectroscopic targets observed before 2002 April, which is known as the Large Scale Structure (LSS) SAMPLE10 within the SDSS collaboration (Blanton et al. 2003c). We select from it 168 958 Main Galaxy Targets (with SDSS flag TARGET/GALAXY or TARGET/GALAXY_BIG) with high-confidence redshifts ($Z_{\text{WARN}} = 0$).

Fig. 1 shows histograms of the basic quantities of our selected sample. The top-right panel shows the galaxy distribution in $r$-band apparent magnitude $r$ after correction for foreground Galactic extinction using the reddening map of Schlegel, Finkbeiner & Davis (1998). The abrupt cut at $\sim 17.77$ mag is caused by the target selection criteria. The top-left panel shows the distribution of the $r$-band Petrosian half-light radius $R_{S0.5}$. The distribution of $R_{S0.5}$, the $r$-band average surface brightness within $R_{S0.5}$, is shown in the bottom-left panel. Since the $r$-band is the reference band of the SDSS for model fitting and target selection, our discussion of sample incompleteness will be based on the photometric properties in this band. The redshifts $z$ of the sample galaxies are obtained from the spectroscopic data, and the distribution of galaxies with respect to $z$ is shown in the bottom-right panel of Fig. 1.

All the galaxies in this sample have Sérsic parameters given by Blanton et al. (2003b). The stellar mass sample by Kauffmann et al. (2003a) contains objects spectroscopically classified as galaxies, with magnitude in the range $14.5 < r < 17.77$, selected from all available spectroscopic observations in the SDSS upcoming Data Release One (DR1). The area covered by this stellar mass sample is almost all contained within our sample, and we obtain a subsample of 118 850 galaxies with stellar masses. This subsample has the same properties as the Main Galaxy Sample except for the smaller sky coverage.

To study the size distribution of galaxies, we need to define a complete sample for which selection effects can be corrected. As discussed in Strauss et al. (2002), the stable TARGET version gives an almost complete sample in the magnitude range $15.0 \leq r \leq 17.77$ and with surface brightness $\mu_{50} \leq 24.5$ mag arcsec$^{-2}$. However, during the commissioning of SDSS, a number of tentative versions of TARGET were used for refining the final TARGET algorithms, and the trial versions of TARGET have small differences in the magnitude and surface brightness limits (see EDR for details). Therefore, to define a complete sample we need to consider selection effects in more detail. Because galaxies with $23.0$ mag arcsec$^{-2} < \mu_{50} < 24.5$ mag arcsec$^{-2}$ are targeted only when the local and global sky values are within $0.05$ mag arcsec$^{-2}$ (Strauss et al. 2002), we set a lower surface brightness limit at $\mu_{\text{lim}} = 23.0$ mag arcsec$^{-2}$. As one can see from the bottom-left panel of Fig. 1, the total number excluded by this selection criterion is very small. Next, to avoid the contamination by bright stars, TARGET rejects bright compact objects with $R_{50} < 2$ arcsec and $r < 15.0$ (15.5 in TARGET v.2.7). Because of this, we exclude all galaxies brighter than 15.0 (15.5 for objects targeted by TARGET v.2.7). As shown in Fig. 1, only a small number of galaxies are excluded by this criterion also. Finally, the magnitude limit ($r_{\text{max}}$) at the faint end varies across the sky in different versions of TARGET. We take this into account by treating $r_{\text{max}}$ as a function of sky position ($\theta$, $\phi$).

A more important effect is that some galaxies are so small (compact) that either their size measurements are seriously affected by the PSFs, or they are misclassified as stars by TARGET. As discussed by Strauss et al. (2002), very few true galaxies at the compact end are missed by the target criteria. However, to take care of the seeing effects, we use only galaxies with angular sizes $R_{50} > D_{\text{min}}$ and we choose $D_{\text{min}} = 1.6$ arcsec (i.e. 4 pixel). This choice, based on the fact that the median seeing condition in SDSS is about 1.5 arcsec, is conservative, because the PSF is known quite accurately. In practice, this cut does not affect our results, as only a relatively small fraction of galaxies is excluded (see the top-left panel of Fig. 1).
Finally we also exclude a small number of galaxies with redshift \( z < 0.005 \), whose distances may be severely contaminated by their peculiar velocities. In summary, our final complete sample includes all galaxies with \( \mu_{50} \lesssim 23.0 \) mag arcsec\(^{-2} \), \( r_{\text{min}}(\theta, \phi) \leq r \leq r_{\text{max}}(\theta, \phi) \), \( R_{50} \gtrsim 1.6 \) arcsec and \( z \gtrsim 0.005 \). This sample contains 138,521 galaxies, of which 99,786 have stellar masses.

2.4 Subsamples of galaxy types

In this paper we also wish to analyse the dependence of the size distribution on galaxy type, so we need to adopt some criteria to classify galaxies.

There are attempts to classify SDSS galaxies into morphological classes through direct inspection of the galaxy images (Shimasaku et al. 2001; Nakamura et al. 2003). While such eye-ball classification should match the original Hubble morphological sequence, it is quite tedious and has so far been carried out only for about 1500 big galaxies in the SDSS. However, it has been suggested that some photometric and spectroscopic properties may be closely correlated with the morphological type, and so can be used as morphology indicators. For example, Shimasaku et al. (2001) show that the concentration \( c \) can be used to separate early-type (E/S0) galaxies from late-type (Sa/b/c, Irr) galaxies. Using about 1500 galaxies with eye-ball classifications, Nakamura et al. (2003) confirmed that \( c = 2.86 \) separates galaxies at Sa/a with a completeness of about 0.82 for both late and early types. For the Sérsic profile (Blanton et al. 2003b), the profile index \( n \) is uniquely related to the concentration parameter, and so the value of \( n \) may also serve as a morphological indicator. Other profile indicators of galaxy type include the exponential and de Vaucouleurs profile likelihoods, \( P_{\text{exp}} \) and \( P_{\text{dev}} \), given in the phot output. Based on the broad-band colours, Strateva et al. (2001) suggested that the colour criterion \( u^* - r > 2.22 \) can separate early types (E/S0/Sa) from late types (Sb/Sc/Irr). Blanton et al. (2003b) found that the colour criterion \( b^i(r - g) \sim 0.7 \) [where \( b^i(g - r) \) is the \( g - r \) colour \( k \)-corrected to the redshift of 0.1] separates galaxies into two groups with distinct properties.

There are also attempts to classify SDSS galaxies according to their spectral types, such as that based on the principal component analysis (Yip et al., in preparation) and that on the 4000 Å spectral index (Kauffmann et al. 2003). While such eye-ball classifications have also neglected possible colour gradients in individual galaxies. The classification based on spectra can be affected by aperture biases due to the finite (3 arcsec in diameter) size of the fibres. Because of these uncertainties, we only divide galaxies into a small number of subsamples according to types. More specifically, we use \( c = 2.86 \) and \( n = 2.5 \) as two basic indicators to separate galaxies into early and late types. With such a separation, most Sa galaxies are included in the late-type category. We also use the colour criterion \( 0.1(g - r) = 0.7 \), for comparison. The \( n \) separation is set at 2.5, the average between exponential profile \( (n = 1) \) and de Vaucouleurs profile \( (n = 4) \), which also gives an early/late ratio similar to that given by the separator \( c = 2.86 \). We adopt the \( 0.1(g - r) \) colour rather than the \( u^* - r^* \) colour, because the \( g \)-band photometry is currently better than the \( u^\prime \)-band photometry in the SDSS and because the \( k \)-correction for the \( u^\prime \) band is very uncertain.

3 THE SIZE DISTRIBUTION OF GALAXIES

In this section, we derive the size distribution as a function of luminosity and stellar mass for galaxies of different types. Specifically, we first bin galaxies of a given type into small bins of absolute magnitude (or mass). We then use a \( V_{\text{max}} \) method to make corrections for the incompleteness due to selection effects, and derive the conditional size distribution function \( \omega(R | M) \) for a given bin. Finally, we investigate the size distribution as a function of luminosity (or stellar mass).

3.1 The \( V_{\text{max}} \) correction of the selection effects

As described in the last section, our sample is selected to be complete only to some magnitude, size and surface brightness limits. In order to obtain the size distribution for the galaxy population as a whole, we must make corrections for these selection effects. In this paper we use the \( V_{\text{max}} \) method to do this.

The basic idea of the \( V_{\text{max}} \) method is to give each galaxy a weight that is proportional to the inverse of the maximum volume (\( V_{\text{max}} \)) within which galaxies identical to the one under consideration can be observed. For a given galaxy with magnitude \( r \), Petrosian half-light radius \( R_{50} \), surface brightness \( \mu_{50} \) and redshift \( z \), the selection criteria described in the last section define the value of \( V_{\text{max}} \) in the following way. First, the magnitude range \( r_{\text{min}} \leq r \leq r_{\text{max}} \) corresponds to a maximum redshift \( z_{\text{max}, \text{min}} \) and a minimum redshift \( z_{\text{min}, \text{max}} \):

\[
d_L(\zeta_{\text{max}, \text{min}}) \leq d_L(1+z)^{0.2(r_{\text{max}}-r_{\text{min}})},
\]

\[
d_L(\zeta_{\text{min}, \text{max}}) \leq d_L(1+z)^{0.2(r_{\text{max}}-r_{\text{min}})},
\]

where \( d_L(z) \) is the luminosity distance at redshift \( z \). Note that we have neglected the effects of \( k \)-correction and luminosity evolution in calculating \( d_L(\zeta_{\text{max}, \text{min}}) \) and \( d_L(\zeta_{\text{min}, \text{max}}) \). In general, the \( k \)-correction makes a given galaxy fainter in the observed \( r \) band if it is put at higher redshift. The luminosity evolution has an opposite effect; it makes galaxies brighter at higher redshift. We found that including these two opposing effects (each is about one magnitude per unit redshift; see Blanton et al. 2003a,c) has a negligible impact on our results.

The surface brightness limit constrains the \( V_{\text{max}} \) of a galaxy mainly through the dimming effect. The maximum redshift at which a galaxy of surface brightness \( \mu_{50} \) at \( z \) can still be observed with the limit surface brightness \( \mu_{50} \sim 23.0 \) is given by

\[
z_{\text{max}, \mu} = (1+z)(23.0-\mu_{50})^{1/5} - 1.
\]

Here, again, \( k \)-correction and luminosity evolution are neglected. We have also neglected possible colour gradients in individual galaxies. The minimum size limit \( D_{\text{min}} \) also defines a maximum redshift \( z_{\text{max}, \mu} \) given by

\[
d_\theta(z_{\text{max}, \mu}) = \frac{R_{50}}{1.67},
\]

where \( d_\theta \) is the angular-diameter distance. The real maximum and minimum redshifts, \( z_{\text{max}} \) and \( z_{\text{min}} \), for a given galaxy are therefore given by

\[
z_{\text{min}} = \min(z_{\text{max}, \mu}, z_{\text{max}, \mu} - 0.005),
\]

\[
z_{\text{max}} = \min(z_{\text{max}, \mu}, z_{\text{max}, \mu}, z_{\text{max}, \mu}),
\]

and the corresponding \( V_{\text{max}} \) is

\[
V_{\text{max}} = \frac{1}{4\pi} \int d\Omega \ f(\theta, \phi) \int_{z_{\text{min}}}^{z_{\text{max}}(\theta, \phi)} \frac{d^2\zeta}{H(z)(1+z)^{2.5}} dz,
\]

where \( H(z) \) is the Hubble constant at redshift \( z \), \( c \) is the speed of light, \( f(\theta, \phi) \) is the sampling fraction as a function of position on the sky, and \( \Omega \) is the solid angle.
The apparent magnitude limit only influences the number of

\[
V_{\text{max}}^* = \frac{V_{\text{max}}}{(4\pi)^{-1} \int d\Omega f(\theta, \phi) \int_{\text{max}(\theta, \phi)}^{\text{min}(\theta, \phi)} d^2 \Omega(z) H^{-1}(z)(1 + z)^{-1} c \, dz.,
\]

which takes values from 0 to 1, and gives the probability that a galaxy with size \( R_{50} \) can be observed at the given absolute magnitude. Given \( N \) galaxies in an absolute magnitude (or mass) bin \( M \pm \Delta M \), the intrinsic conditional size distribution \( f(R \mid M) \) can be estimated from

\[
f(R \mid M) \propto \sum_{i=1}^{N} \frac{V_{\text{max}}^*}{R_{i}} \quad \text{if } R - dR < R_i < R + dR,
\]

where \( R_i \) and \( V_{\text{max}}^* \) are the radius and the value of \( V_{\text{max}}^* \) for the \( i \)th galaxy.

### 3.2 Size distribution: dependence on luminosity

In this subsection, we study the size distribution as a function of luminosity for galaxies of different type. The absolute magnitude is calculated from the observed apparent magnitude \( m \) using

\[
M = m - \text{DM}(z) + 5 - k(z),
\]

where \( z \) is the redshift of the galaxy, \( \text{DM}(z) \) is the distance modulus and \( k(z) \) is the \( k \)-correction. The distances are calculated from redshifts using a cosmology with mass density \( \Omega_0 = 0.3 \), cosmological constant \( \Omega_\Lambda = 0.7 \) and Hubble constant \( h = 0.7 \). The \( k \)-correction is calculated based on the study of Blanton et al. (2003a).

In Figs 2 and 3 we show the histograms of Petrosian half-light radius \( R_{50} \) for galaxies of different absolute magnitudes and types. We use \( c = 2.86 \) to separate galaxies, in which case 32 per cent of them are included in the early types. Galaxies of a given type are further divided into absolute magnitude bins with a width of 0.5 mag. The dotted histograms show the observed size distributions, obtained by directly counting the numbers of galaxies in given size bins. The intrinsic distributions, obtained by using the \( V_{\text{max}}^* \) correction (see equation 10), are shown as the solid histograms. All the histograms are normalized to unit area in the space of log \( (R_{50}) \).

As one can see, for both late- and early-type galaxies, the intrinsic size distributions can be approximated reasonably well by a log-normal function. As we will see later, this type of distribution in sizes is also motivated by theoretical considerations. We therefore make the assumption that \( f(R \mid M) \) has a log-normal form,

\[
f(R, \bar{R}(M), \sigma_{ln,R}(M)) = \frac{1}{\sqrt{2\pi} \sigma_{ln,R}(M)} \exp \left\{ -\frac{\ln^2[R/\bar{R}(M)]}{2\sigma_{ln,R}^2(M)} \right\} \frac{dR}{\bar{R}},
\]

which is characterized by the median \( \bar{R}(M) \) and the dispersion \( \sigma_{ln,R}(M) \). We use a maximum-likelihood method to estimate \( \bar{R} \) and \( \sigma_{ln,R} \) at each magnitude bin. The procedure goes as follows. For a sample of \( N \) galaxies (in a certain absolute magnitude bin) with sizes \( \{R_i\}_{i=1}^{N} \) and conditional maximum volumes \( \{V_{\text{max}}^*\}_{i=1}^{N} \), the likelihood for the size distribution is

\[
-L(\bar{R}, \sigma_{ln,R}) = \prod_{i=1}^{N} \frac{1}{V_{\text{max}}^*} \frac{f(R_i, \bar{R}, \sigma_{ln,R})}{f_{\text{min}}(R_i, \sigma_{ln,R})} dR
\]

Figure 2. Histograms of Petrosian half-light radius \( R_{50} \) (in the r band) for early-type (c > 2.86) galaxies in different Petrosian r-band absolute magnitude bins. The dotted histograms show the raw distribution, while the solid histograms show the results after \( V_{\text{max}}^* \) correction for selection effects. The solid curves are obtained by fitting the size to a log-normal distribution through the maximum-likelihood method.

where \( R_{\text{min}} \) and \( R_{\text{max}} \) are the minimum and maximum radii that can be observed for the luminosity bin under consideration, and \( f(R, \bar{R}, \sigma_{ln,R}) \) is the log-normal function with median \( \bar{R} \) and dispersion \( \sigma_{ln,R} \) given in equation (12). By maximizing this likelihood function, we obtain the best estimates of \( \bar{R} \) and \( \sigma_{ln,R} \) for each magnitude bin. The solid curves in Figs 2 and 3 show the results of the log-normal functions so obtained. As one can see, they provide very good fits to the solid histograms.

Fig. 4 shows \( \bar{R} \) (upper panel) and \( \sigma_{ln,R} \) (lower panel) against the absolute magnitude. Triangles and squares denote the results for late- and early-type galaxies, respectively. The error bars are obtained from the scatter among 20 bootstrap samples. The small error bars show the statistics that one can get from the current sample. The number of faint early-type galaxies is still too small to give any meaningful results (see the panel of \( M_r = 18.25 \) in Fig. 1). This small number may not mean that the number of faint elliptical galaxies is truly small; it may just reflect our definition of early- and late-type galaxies. Indeed, faint elliptical galaxies seem to have surface brightness profiles better described by an exponential than a \( R^{1/4} \) law (Andredakis, Peletier & Balcacis 1995; Kormendy & Bender 1996), and so they will be classified as ‘late-type’ galaxies according to the criterion because of their small concentration.

As shown in Fig. 4, the dependence of \( \bar{R} \) on the absolute magnitude is quite different for early- and late-type galaxies. In general, the increase of \( \bar{R} \) with luminosity is faster for early-type galaxies. The \( R - M \) relation can roughly be described by a single power law for bright early-type galaxies, while for late-type galaxies the relation is significantly curved, with brighter galaxies showing a faster increase of \( \bar{R} \) with \( M \). In the luminosity range where \( \bar{R} \) and \( \sigma_{ln,R} \) can be determined reliably, the dispersion has a similar trend with \( M \).
Size distribution of SDSS galaxies

Figure 3. The same as Fig. 2, but for late-type \((c < 2.86)\) galaxies.

Figure 4. The median and dispersion of the distribution of Petrosian half-light radius \(R_{50}\) (in the \(r\) band), as functions of \(r\)-band Petrosian absolute magnitude. Results for late-type \((c < 2.86)\) and early-type \((c > 2.86)\) galaxies are shown as triangles and squares, respectively. The error bars represent the scatter among 20 bootstrap samples. The solid curves are the fit of the \(R-M\) and \(\sigma_{\ln R-M}\) relations by equations (14), (15) and (16).

for both early- and late-type galaxies. An interesting feature in \(\sigma_{\ln R}\) is that it is significantly smaller for galaxies brighter than \(-20.5\) mag (in the \(r\) band). As we will discuss in Section 4, these observational results have important implications for the theory of galaxy formation.

To quantify the observed \(R-M\) and \(\sigma_{\ln R-M}\) relations, we fit them with simple analytic formulae. For early-type galaxies, we fit \(R-M\) by

\[
\log(\bar{R}/\text{kpc}) = -0.4aM + b, \tag{14}
\]

where \(a\) and \(b\) are two fitting constants. For late-type galaxies, we fit the size–luminosity relation and its dispersion by

\[
\log(\bar{R}/\text{kpc}) = -0.4\alpha M + (\beta - \alpha) \log[1 + 10^{-0.4(M-M_0)}] + \gamma \tag{15}
\]

\[
\sigma_{\ln R} = \sigma_2 + \frac{(\sigma_1 - \sigma_2)}{1 + 10^{-0.8(M-M_0)}}, \tag{16}
\]

where \(\alpha\), \(\beta\), \(\gamma\), \(\sigma_1\), \(\sigma_2\) and \(M_0\) are fitting parameters. Note that the value of \(M_0\) used in equation (15) is determined by fitting the observed \(\sigma_{\ln R-M}\) relation (equation 16), because the fit of the \(R-M\) relation is not very sensitive to the value of \(M_0\). Thus, the relation between \(R\) and the luminosity \(L\) is \(R \propto L^\alpha\) for early-type galaxies. For late-type galaxies, \(R \propto L^\beta\), \(\sigma_{\ln R} = \sigma_1\) at the faint end \((L < L_0)\), where \(L_0\) is the luminosity corresponding to \(M_0\), and \(R \propto L^\gamma\), \(\sigma_{\ln R} = \sigma_2\) at the bright end \((L \gg L_0)\). We use the least-squares method to estimate the fitting parameters and the results are given in Table 1. These fitting results are also plotted as solid lines in Fig. 4.

We have also analysed the size distribution as a function of luminosity in finer ranges of \(c\). Specifically, we further divide late-type galaxies \((c < 2.86)\) into three subsamples containing equal numbers
of galaxies, and early-type galaxies ($c > 2.86$) into two equal subsamples. The ranges of $c$ and the results for $R$ and $\sigma_{\text{fl}}$ for these subsamples are shown in Fig. 5. As we can see, the $\bar{R}$–$M$ relation depends systematically on $c$: galaxies with higher $c$ show a steeper relation. However, the difference between the two early-type samples is quite small, except for the two faintest bins where the statistic is quite poor.

As discussed in Section 2.2, the Sérsic half-light radii $R_{50,5}$ given by Blanton et al. (2003b) have the merit of being corrected for PSF and, unlike the Petrosian magnitude, the Sérsic magnitude has also the merit of including the total flux of a galaxy. We therefore also made analyses based on the Sérsic quantities. Here we use $n = 2.5$ to separate late- and early-type galaxies. In this separation, about 36 per cent of the galaxies are classified as early types. Fig. 6 shows the results of $\bar{R}$ and $\sigma_{\text{fl}}$ for the Sérsic quantity $R_{50,5}$. We have also fitted the size–luminosity relations to the functional form given by equations (14), (15) and (16), and the fitting parameters are listed in Table 1. Comparing these results with those shown in Fig. 4, we see that early-type galaxies here have systematically bigger half-light radii for given luminosity. This is caused by differences between the Petrosian and Sérsic quantities. For a galaxy with pure de Vaucouleurs profile, the Petrosian magnitude includes about 80 per cent

Figure 5. The median and dispersion of the $R_{50}$ (in the $r$ band) distribution, as a function of $r$-band Petrosian absolute magnitude, for galaxies in fine bins of $c$.

Figure 6. The median and dispersion of the distribution of the Sérsic half-light radius $R_{50,5}$ (in the $r$ band) as functions of $r$-band absolute Sérsic magnitude. Here a galaxy is separated into early or late type according to whether its Sérsic index $n$ is larger or smaller than 2.5. The error bars represent the scatter among 20 bootstrap samples. The solid curves are the fit of the $\bar{R}$–$M$ and $\sigma_{\text{fl}}$–$M$ relations by equations (14), (15) and (16).

of the total flux, while the Petrosian half-light radius is only about 70 per cent of the real half-light radius. Note that our derived slopes for the $R$–$L$ relation in both cases are consistent with the result $R \propto L^{0.63}$ obtained by Bernardi et al. (2003b) where yet another photometric system is used. For late-type galaxies with exponential light profiles, no significant difference is found between these two systems, because the Petrosian magnitude includes almost all the total flux and the half-light radius is approximately the same as the true half-light radius. Although our results show a significantly curved $R$–$L$ relation for late-type galaxies, a simple power law is usually used as an assumption in previous studies due to the small samples. However, the results are generally consistent; for example, the relation obtained by de Jong & Lacey (2000) is $R \propto L^{0.23}$ in $I$ band.

Expanding on this, we have analysed the size distribution as a function of luminosity in finer bins of $n$. We divide the late-type sample ($n < 2.5$) into three equal subsamples, and the early-type sample ($n > 2.5$) into two equal subsamples. The ranges of $n$ for these subsamples and the fitting results are shown in Fig. 7. These results should be compared with those shown in Fig. 5. While
galaxies with higher \( n \) do show a steeper \( \bar{R} - M \) relation, the change of the trend with \( n \) is less systematic than with \( c \). It seems that galaxies are separated into two groups at \( n \approx 1.7 \), and galaxies in each group have similar \( \bar{R} - M \) relations, independent of \( n \). As shown by the two-dimensional distribution of galaxies in the space spanned by \( n \) and the \( 0.1(g - r) \) colour (Blanton et al. 2003b), the cut at \( n = 1.7 \) roughly corresponds to a colour cut at \( 0.1(g - r) \approx 0.7 \). The latter cut appears to separate E/S0/Sa from Sb/Sc/Irr galaxies, as discussed in Section 2.4.

For comparison, we consider separating galaxies according to the colour criterion \( 0.1(g - r) = 0.7 \). The results are shown in Fig. 8. In this case, since most Sa galaxies are classified as early-type galaxies, there are fewer bright late-type galaxies. Moreover, we begin to see faint red galaxies (presumably faint ellipticals), which would be classified as ‘late-type’ galaxies by the \( c \) and \( n \) criteria, because of their low concentrations. As one can see, the late-type galaxies show approximately the same statistical properties as those in the \( c \) and \( n \) classifications. This is also true for bright early-type galaxies. Red galaxies with \( M_r \approx -20 \) seem to follow a parallel trend to late-type galaxies, although they are smaller at given absolute magnitude. This is consistent with the fact that many dwarf ellipticals show exponential surface brightness profiles, have small sizes, and have size–luminosity scaling relations similar to that of spiral galaxies (e.g. Caon, Capaccioli & D’Onofrio 1993; Kormendy & Bender 1996; Guzman et al. 1997; Prugniel & Simien 1997; Gavazzi et al. 2001). Faint red galaxies with \( M_r > -19 \) seem to have almost constant size. Note that \( \sigma_{\ln R-M} \) show similar dependence on \( M \) for both red and blue galaxies.

Since most of the concentrated galaxies have red colours, while galaxies with low concentrations can have both blue and red colours, it is interesting to examine the properties of galaxies selected by both colour and \( n \). To do this, we consider a case where galaxies with \( n < 2.5 \) are divided further into two subsamples according to the colour criterion \( 0.1(g - r) = 0.7 \). The results are shown in Fig. 9. As we can see, B-type galaxies (with low \( n \) and red colour) show an \( R-M \) relation that is closer to that of A-type (high-\( n \)) galaxies than that of C-type (blue and low-\( n \)) galaxies. Note again that faint red galaxies have sizes almost independent of luminosity. The \( \sigma_{\ln R-M} \) relations are similar for all three cases.
So far our discussion has been based on the $r$-band data. If galaxies possess significant radial colour gradients, the size of a galaxy may be different in different wavebands. Furthermore, if galaxies have different colours, the size distribution as a function of luminosity may also be different in different wavebands. To test how significant these effects are, we have analysed the size distributions separately in the SDSS $g$, $i$, and $z$ bands, using either the absolute magnitudes in the corresponding band or the absolute magnitudes in the $r$ band to bin galaxies into luminosity subsamples. The results are qualitatively the same as derived from the $r$-band data. Similar conclusions for early-type galaxies have been reached by Bernardi et al. (2003b). As an example, we show in Fig. 10 the results based on Sérsic radii and Sérsic $z$-band magnitudes. The galaxies are also separated into late and early type by the $r$-band Sérsic index $n = 2.5$. The results of fitting the $R$–$M$ and $\sigma_{\text{in,}R}$–$M$ relations are presented in Table 1. Because of the long wavelength involved in the $z$-band photometry, the quantities in this band may better reflect the properties of the stellar mass (e.g. Kauffmann et al. 2003b).

### 3.3 Size distribution: dependence on stellar mass

In this subsection, we study the size distribution of galaxies as a function of stellar mass. We use the data obtained by Kauffmann et al. (2003). Fig. 11 shows the results based on the $z$-band Sérsic half-light radii. To quantify the mass dependence of $R$ and $\sigma_{\text{in,}R}$, we fit the $R$–$M$ relation for the early-type galaxies by

$$R(kpc) = b \left( \frac{M}{M_\odot} \right)^\alpha.$$  

(17)

For late-type galaxies, we fit $R$–$M$ and $\sigma_{\text{in,}R}$–$M$ by

$$R(kpc) = \gamma \left( \frac{M}{M_\odot} \right)^\alpha \left( 1 + \frac{M}{M_0} \right)^{\beta - \alpha}$$  

(18)

and

$$\sigma_{\text{in,}R} = \sigma_z + \frac{(\sigma_1 - \sigma_2)}{1 + (M/M_0)^2}.$$  

(19)

respectively, where $M$ is the stellar mass, and $\alpha$, $\beta$, $\gamma$, $\sigma_1$, $\sigma_2$, $M_0$, $a$, and $b$ are all fitting parameters. Those parameters have the same meaning as in equations (14), (15) and (16) except that stellar mass is used instead of luminosity. The values of these parameters given by a least-squares fit to the data are also listed in Table 1. The fitting results are shown as the solid curves in Fig. 11. Here, similar to the size–luminosity relation, $M_0$ is the characteristic mass at which $\sigma_{\text{in,}R}$ changes significantly and is about $10^{10.6} M_\odot$. For late-type galaxies, the low-mass galaxies ($M \ll M_0$) have $R \propto M^{0.14}$ and $\sigma_{\text{in,}R} = 0.47$, and the high-mass galaxies ($M \gg M_0$) have $R \propto M^{0.30}$ and $\sigma_{\text{in,}R} = 0.34$. The early-type galaxies follow the relation $R \propto M^{0.56}$. The power indices $a$, $\alpha$, and $\beta$ are smaller for the mass than for the luminosity, because the mass-to-light ratio is systematically higher for galaxies with higher luminosity.

For early-type galaxies, the power index $a = 0.56$ implies that the average surface mass density $\Sigma_0$ within the half-light radius is roughly a constant, which is shown directly in Fig. 12. Here we have assumed that no mass-to-light ratio gradient exists in the $z$ band so that the half-light radius also encloses half of the stellar mass. Moreover, since the stellar mass is derived by multiplying the Petrosian luminosity with the model-derived mass-to-light ratio $M/L$ (Kauffmann et al. 2003), the Petrosian half-light radius $R_{50}$ is used here in calculating the $I_{50}$. As we will discuss in Section 5, these results have important implications for the formation of elliptical galaxies.

![Figure 10](https://example.com/figure10.png)

**Figure 10.** The median and dispersion of the distribution of Sersic half-light radius $R_{50,z}$ in the $z$ band, as a function of $z$-band Sersic absolute magnitude. Triangles represent results for late-type galaxies (here defined to be those with $n < 2.5$), while the squares are for early-type galaxies (with $n > 2.5$). The error bars represent the scatter among 20 bootstrap samples. The solid curves are the fit of the $R$–$M$ and $\sigma_{\text{in,}R}$–$M$ relations by equations (14), (15) and (16).

![Figure 11](https://example.com/figure11.png)

**Figure 11.** The median and dispersion of the distribution of Sersic half-light radius $R_{50,z}$ in the $z$ band, as a function of stellar mass. Triangles represent results for late-type galaxies (here defined to be those with $n < 2.5$), while the squares are for early-type galaxies (with $n > 2.5$). The error bars represent the scatter among 20 bootstrap samples. The solid curves are the fit of the $R$–$M$ and $\sigma_{\text{in,}R}$–$M$ relations by equations (17), (18) and (19).
3.4 The surface brightness distribution

The intrinsic surface brightness $\mu_{50}$ of a galaxy is linked to its size $R_{50}$ through

$$\mu_{50}(\text{mag arcsec}^{-2}) = M(\text{mag}) + 5 \log R_{50}(\text{kpc}) + 38.57,$$

(20)

where $M$ represents the absolute magnitude. Thus, the log-normal size distribution for a given luminosity implies that the surface brightness distribution at a given luminosity is normal. In this case, we may obtain the median and dispersion of the surface brightness distribution directly from the size distribution through equation (20). However, since the width of our magnitude bins (0.5 mag) is finite, the conversion is not accurate. We therefore recalculated the median and dispersion of the surface brightness distribution in each magnitude bin by using the same maximum-likelihood method as for the size distribution. As an example, we show the $r$-band surface brightness distribution in Fig. 13. The surface brightness used here is defined in the Sersic system, i.e. the average surface brightness inside the Sersic half-light radius, but galaxies are labelled by their Petrosian magnitudes. The reason for this is that the luminosity function we are going to use to derive the integrated surface brightness distribution is based on Petrosian magnitudes. As before, galaxies are separated into late- and early-type galaxies at $c = 2.86$. As one can see from Fig. 13, the brighter late-type galaxies have systematically higher surface brightness, while the trend is the opposite for bright early-type galaxies. This is the well-known Kormendy relation (Kormendy 1977). Another feature clearly seen is that the mean value of the surface brightness is almost independent of luminosity for bright late-type galaxies, which is consistent with the Freeman disc (Freeman 1970). For dwarf late-type galaxies, the surface brightness shows a strong increase with increasing luminosity in the range $-20 < M_r < -18$. The median value of the surface brightness is consistent with being constant in the luminosity range $-16 < M_r < -18$. However, this result should be treated with caution, because the median value is already quite close to the limit.

23.0 mag arcsec$^{-2}$. Any incompleteness near 23.0 mag arcsec$^{-2}$ can bias the median to a lower value (i.e. higher surface brightness).

With the conditional surface brightness distribution function $f(\mu_{50} \mid M)$, we can calculate the number density of galaxies at any given surface brightness $\mu_{50}$ by integrating over the luminosity function $\phi(M)$:

$$\phi(\mu_{50}) = \int \phi(M) f(\mu_{50} \mid M) \, dM.$$  (21)

The luminosity functions of early- and late-type galaxies separated at $c = 2.86$ have recently been given by Nakamura et al. (2003) based on the Petrosian magnitudes. As shown in Fig. 13, our conditional surface brightness distribution is reliably determined only in the luminosity range $-24 < M_r < -16$ for late-type galaxies, and in $-24 < M_r < -19$ for early-type galaxies. Therefore, we set the bright end of the integration in equation (21) to be $M_r = -24$ and carry out the integration from a number of low-luminosity limits. The median and dispersion of the surface brightness distribution at any given magnitude are obtained from a linear interpolation between adjacent magnitude bins. The results are shown on Fig. 14 with the faint-end limits labelled on the corresponding curves. The two vertical lines at 18.0 and 23.0 mag arcsec$^{-2}$ correspond to the observational surface brightness limits (defined in Petrosian system) of our sample. The bright limit 18.0 mag arcsec$^{-2}$ corresponds to the brightest galaxies ($r = 15.0$) with sizes at the lower limit (1.6 arcsec).

As one can see from the figure, there may be many compact early-type galaxies that are not included in our sample. For late-type galaxies, the surface brightness shows a narrow normal distribution for bright galaxies (i.e. the Freeman disc). When more dwarf galaxies are included, low surface brightness galaxies may contribute a
large fraction of the total numbers of galaxies. Unfortunately, the current data cannot give a stringent constraint on the number density of low surface brightness galaxies because the results for very faint galaxies (\( M_r > -16 \)) are uncertain. However, the fact that galaxies with the lowest surface brightness are predominantly of low luminosity suggests that such low surface brightness galaxies contribute little to the luminosity density of the Universe. A similar conclusion has been reached in earlier analysis (e.g. de Jong & Lacey 2000; Blanton et al. 2001; Cross & Driver 2002).

4 THEORETICAL EXPECTATIONS

In the preceding sections we have seen that the current SDSS data can be used to derive good statistics for the size distribution of galaxies and its dependence on luminosity, stellar mass, concentration and colour. In this section, we examine whether or not these observational results can be accommodated in the current paradigm of galaxy formation.

4.1 Late-type galaxies

Let us start with late-type (spiral) galaxies. A spiral galaxy generally consists of a rotationally supported thin disc, and an ellipsoidal bulge that rotates relatively slowly.

4.1.1 The disc component

According to current theory of galaxy formation, galaxy discs are formed as gas with some initial angular momentum cools and contracts in dark matter haloes. Our model of disc formation follows that described in Mo, Mao & White (1998, hereafter MMW). The model assumes spherical dark haloes with density profile given by Navarro, Frenk & White (1997, hereafter NFW):

\[
\rho(r) = \frac{\rho_0}{(r/r_\text{c})(1 + r/r_\text{c})^2},
\]

where \( r_\text{c} \) is a characteristic radius and \( \rho_0 \) is a characteristic density. The halo radius \( r_{200} \) is defined so that the mean density within it is 200 times the critical density. It is then easy to show that \( r_{200} \) is related to the halo mass \( M_h \) by

\[
r_{200} = \frac{G^{1/3} M_h^{1/3}}{[10H(z)]^{1/2}},
\]

where \( H(z) \) is the Hubble constant at redshift \( z \). The total angular momentum of a halo, \( J \), is usually written in terms of the spin parameter,

\[
\lambda = J / (E)^{1/2} G^{-1/2} M_h^{-5/2},
\]

where \( E \) is the total energy of the halo. \( N \)-body simulations show that the distribution of halo spin parameter \( \lambda \) is approximately log-normal,

\[
p(\lambda) \, d\lambda = \frac{1}{\sqrt{2\pi}\sigma_{\ln \lambda}} \exp \left[ -\frac{\ln^2(\lambda / \bar{\lambda})}{2\sigma^2_{\ln \lambda}} \right] \frac{d\lambda}{\lambda},
\]

with \( \bar{\lambda} \approx 0.04 \) and \( \sigma_{\ln \lambda} \approx 0.5 \) (Warren et al. 1992; Cole & Lacey 1996; Lemson & Kauffmann 1999).

We assume that the disc that forms in a halo has mass \( M_d \) related to the halo mass by

\[
M_d = m_d M_h,
\]

and has angular momentum \( J_d \) related to the halo spin by

\[
J_d = j_d J,
\]

where \( m_d \) and \( j_d \) give the fractions of mass and angular momentum in the disc. Assuming that the disc has an exponential surface density profile and that the dark halo responds to the growth of the disc adiabatically, the disc scalelength \( R_d \) can be written as

\[
R_d = \frac{1}{\sqrt{2}} \left( \frac{j_d}{m_d} \right) \lambda x_{200} f_i,
\]

where \( f_i \) is a factor that depends both on halo profile and on the action of the disc (see MMW for details). As shown in MMW, for a given halo density profile, \( f_i \) depends on both \( m_d \) and \( \lambda_d \equiv (j_d/m_d) \lambda \), but the dependence on \( \lambda_d \) is not very strong. Thus, if \( j_d/m_d \) is constant, the log-normal distribution of \( \lambda \) will lead to a size distribution that is roughly log-normal.

4.1.2 The bulge component

Our empirical knowledge about the formation of galaxy bulges is still very limited (e.g. Wyse, Gilmore & Franx 1997). Currently there are two competing scenarios in the literature: one is the merging scenario, and the other is based on disc instability.

In the merging scenario, galaxy bulges, like elliptical galaxies, are assumed to form through the mergers of two or more galaxies (Toomre & Toomre 1972). Subsequent accretion of cold gas may form a disc around the existing bulge, producing a bulge/disc system like a spiral galaxy (e.g. Kauffmann, White & Guiderdoni 1993; Kauffmann 1996; Baugh, Cole & Frenk 1996; Jablonka, Martin & Arimoto 1996; Gnedin, Norman & Ostriker 2000). In this scenario, the formation of the bulge is through a violent process prior to the formation of the disc, and so the properties of the bulge component are not expected to be closely correlated with those of the disc that forms subsequently.
In the disc-instability scenario, low angular momentum material near the centre of a disc is assumed to form a bar due to a global instability; the bar is then transformed into a bulge through a buckling instability (e.g. Kormendy 1989; Norman, Sellwood & Hasan 1996; Mao & Mo 1998; van den Bosch 1998; Noguchi 2000). The first of these instabilities is well documented through direct simulation, the second less so. According to both N-body simulations (Efstathiou, Lake & Negroponte 1982) and analytic models (e.g. Christodoulou, Shlosman & Tohline 1995), discs may become globally unstable when

$$\epsilon \equiv \frac{V_\text{m}}{(G M_\text{d}/R_\text{d})^{1/2}} < \epsilon_0,$$

(29)

where $V_\text{m}$ is the maximum rotation velocity of the disc, and $\epsilon_0 \sim 1$. As discussed in MMW, for a disc in a NFW halo, this criterion can be approximately be written as $m_\text{d} > \lambda_\text{d}$. Thus, for given $\lambda_\text{d}$, there is a critical value $m_{\text{d}, c}$ for $m_\text{d}$ above which the disc is unstable. If the overall stellar mass fraction $m_\text{s}$ (defined as the ratio of total stellar mass to total halo mass) is smaller than $m_{\text{d}, c}$, the disc is stable and there is no bulge formation in this scenario. In this case, $m_\text{d} = 0$ and $m_\text{d} = m_\text{s}$. Here, $m_\text{s}$ is the bulge fraction, which links the mass of the bulge to the halo mass,

$$M_\text{b} = m_\text{s} M_\text{h}.$$  

(30)

If $m_\text{d} > m_{\text{d}, c}$, we assume that the bulge mass is such that the disc has $\epsilon = \epsilon_0$, i.e. the disc is marginally unstable. In this case, $m_\text{d} = m_{\text{d}, c}$ and $m_\text{h} = m_\text{d} - m_{\text{d}, c}$. Note that the gravity of the bulge component must be taken into account when calculating $\epsilon$. To do this, we include a bulge component in the gravitational potential following MMW. For given $m_\text{d}$ and $\lambda_\text{d}$, we then solve for $m_\text{h}$ and $m_\text{d}$ iteratively.

To proceed further, we assume the angular momentum of the bulge to be negligible. There are two ways in which the bulge may end up with little angular momentum: the first is that it formed from halo material that initially had low specific angular momentum; the second is that the bulge material lost most of its angular momentum to the halo and the disc during formation. In the first case, we assume that the specific angular momentum of the final disc is the same as that of the dark matter, so that $J_\text{d} = m_\text{d}$. In the second case, the final angular momentum of the disc depends on how much of the bulge’s initial angular momentum it absorbs. Numerical simulations by Klypin, Zhao & Somerville (2002) suggest that angular momentum loss is primarily to the disc for bulges that form through bar instability. In general, we assume a fraction of $f_0$ of the bulge angular momentum is transferred to the disc component, and so $J_\text{d} = (m_\text{d} + f_0 m_\text{b})$. Thus the effective spin parameter for the disc is

$$\lambda_\text{d} = \lambda (1 + f_0 m_\text{b}/m_\text{d}),$$

(31)

and we use this spin to calculate the disc size.

To complete our description of the disc component, we also need to model the size of the bulge. Since current models of bulge formation are not yet able to make reliable predictions about the size–mass relation, we have to make some assumptions based on observation. Observed galaxy bulges have many properties similar to those of elliptical galaxies. We therefore consider a model in which galaxy bulges follow the same size–mass relation as early-type galaxies. Specifically, we assume that bulges with masses higher than $2 \times 10^{10} M_\odot$ have de Vaucouleurs profiles and have a size–mass relation given by equation (17). For less massive bulges, we adopt exponential profiles and two models for the size–mass relation. In the first model, low-mass bulges follow a size–mass relation that is parallel to that of faint late-type galaxies but has a lower zero-point (so that it joins smoothly to the relation for giant ellipticals at $M = 2 \times 10^{10} M_\odot$), i.e.

$$\log(R_\text{e}/\text{kpc}) = \begin{cases} 0.56 \log(M_\text{h}) - 5.54 & \text{for } M_\text{h} > 2 \times 10^{10} M_\odot, \\ 0.14 \log(M_\text{h}) - 1.21 & \text{for } M_\text{h} < 2 \times 10^{10} M_\odot, \end{cases}$$

(32)

where $R_\text{e}$ is the effective radius of the bulge. This model is motivated by the fact that dwarf ellipticals obey a size–luminosity relation roughly parallel to that of spiral galaxies (Kormendy & Bender 1996; Guzman et al. 1997, see figs 7 to 9). In the second model, we assume a size–mass relation that is an extrapolation of that for the massive ellipticals, i.e.

$$\log(R_\text{e}/\text{kpc}) = 0.56 \log(M_\text{h}) - 5.54.$$  

(33)

In this case, faint bulges are small and compact, like compact ellipticals (Kormendy 1985; Guzman et al. 1997). For simplicity, we do not consider the scatter in the size–mass relation in either case.

With the mass and size known for both the disc and bulge components, we can obtain the surface density profile of the model galaxy by adding up the surface density profiles of the two components:

$$I(r) = I_\text{d}(r) + I_\text{b}(r),$$

(34)

from which one can estimate the half-mass radius for each model galaxy.

### 4.1.3 The value of $m_\text{b}$

If all the gas in a halo can settle to the halo centre to form a galaxy, then $m_\text{g} \sim \Omega_{0,0} / \Omega_0$. For the cosmological model adopted here this would imply $m_\text{g} \sim 0.13$, much larger than most estimates of the baryon fraction in galaxies. In reality, not all the gas associated with a halo may settle into the central galaxy, because feedback from star formation provides a heat source that may expel some of it. Based on such considerations, we consider a feedback model in which the mass fraction $m_\text{g}$ in a halo of mass $M_\text{h}$ is

$$m_\text{b} = \frac{m_0}{1 + (M_\text{h}/M_\alpha)^{-\alpha}}.$$  

(35)

where $M_\alpha$ is a characteristic mass, $\alpha$ is a positive index, and $m_0$ is a constant representing the mass fraction in systems with $M_\text{h} \gg M_\alpha$ (e.g. White & Frenk 1991). We set $m_0 = \Omega_{0,0} / \Omega_0 = 0.13$, so that $m_\text{b}$ is suppressed for small haloes. Galaxy wind models suggest that the circular velocity corresponding to $M_\text{h}$ is about $150 \text{ km s}^{-1}$, i.e. $M_\alpha \sim 10^{12} M_\odot$, and the value of $\alpha$ is 2/3. If the intergalactic medium is preheated to a high entropy, then $\alpha$ is about 1 (Mo & Mao 2002).

### 4.1.4 Specific models

To summarize, there are four key ingredients in the scenarios described above. The first is the feedback process, which gives the mass fraction $m_\text{b}$. We use the parametrized form given in equation (35) to model this process, and the model parameters are $m_0$, $\alpha$ and $M_\alpha$. The second is the bulge/disc ratio $B/D$. This ratio is assumed to be either uniform on the interval [0, 1] or given by the instability criterion. The third is the amount of angular momentum transfer between bulge and disc components, as characterized by the parameter $f_0$ in equation (31). The fourth is the size–mass relation of small bulges characterized by equation (32) or (33).

To consider these different possibilities, we have chosen seven models as illustrations. In the following we summarize these models in some detail; their parameters are listed in Table 2.
Table 2. Parameters for the different models itemized in Section 4.1.4.

**Model I:** Here the mass fraction is chosen to be a constant $m_g = 0.05$, in contrast to the feedback model where $m_g$ changes with halo mass, and the $B/D$ ratio is assumed to be random in the interval [0, 1]. Discs are generated according to the model described in Section 4.1.1, and bulges are assigned sizes according to equation (32). No angular momentum transfer from the bulge component to the disc is assumed.

**Model II:** Here $m_g$ is assumed to follow equation (35), with $m_0 = 0.13$, $\alpha = 2/3$ and $M_c = 10^{12} M_\odot$. Other assumptions are the same as for Model I.

**Model III:** In this model $m_g$ is assumed to follow equation (35), with $m_0 = 0.13$, $\alpha = 2/3$ and $M_c = 10^{12} M_\odot$. Bulges are generated based on disc instability. All of the initial angular momentum of the bulge is assumed to be transferred to the disc, i.e. $f_J = 1$. The size–mass relation of the bulge component follows equation (32).

**Model IV:** This model is the same as Model III, except that there is no angular momentum transfer, i.e. $f_J = 0$.

**Model V:** This model is also the same as Model III, except that half of the initial angular momentum of the bulge material is transferred into the disc (i.e. $f_J = 0.5$).

**Model VI:** This model is the same as Model V, except that $\alpha$ is assumed to be 1 instead of 2/3.

**Model VII:** This model is the same as Model V, except that the size–mass relation of the bulge is equation (33) instead of equation (32).

4.1.5 Model predictions

We use Monte Carlo simulations to generate galaxy samples for each of the models described above. To do this, we first use the Press–Schechter formalism (Press & Schechter 1974) to generate 50,000 dark matter haloes at redshift zero with masses (parametrized by circular velocity $V_c$) in the range $35 \text{ km s}^{-1} < V_c < 350 \text{ km s}^{-1}$ and with a log-normal spin parameter distribution with $\bar{\lambda} = 0.03$ and $\sigma_{\ln \lambda} = 0.45$ (see equation 25).

We then use equations (23)–(35) to calculate the sizes and masses of the disc and bulge for each galaxy. Finally, we combine the disc and bulge of each galaxy to calculate its half-mass radius. As for the observational data, we sort galaxies into stellar mass bins and calculate the median and dispersion of the size distribution as functions of stellar mass.

Fig. 15 compares results for the seven models with the observational data for the $z$-band Sérsic half-light radii of late-type galaxies.
(n < 2.5) as a function of stellar masses. As one can see, if \( m_B \) is assumed to be a constant (Model I), the predicted median size–mass relation is \( \bar{R} \propto M^{1/3} \), which is completely inconsistent with observations of low-mass galaxies. The predicted \( \sigma_R \) is also too large. When \( m_B \) is assumed to change with halo mass as suggested by the feedback scenario (Model II), the predicted shape of \( \bar{R} – M \) is similar to that observed for low-mass galaxies, but the predicted median sizes are too small for high-mass galaxies. The predicted dispersion is also too big for high-mass galaxies. If bulges are assumed to form through disc instability and if \( f_J = 1 \) (Model III), the predicted scatter follows the observations, but the predicted median sizes are too big for massive galaxies. On the other hand, if no angular momentum is transferred, i.e. \( f_J = 0 \) (Model IV), the predicted median size is smaller at the high-mass end and the predicted scatter becomes systematically higher. To match the observed behaviour of the median and the dispersion simultaneously, \( f_J \sim 0.5 \) seems to be required (Model V). Changing the value of \( \alpha \) from 2/3 to 1 (Model VI) gives a median size that is slightly too high for low-mass galaxies. If the size–mass relation for small bulges is assumed to be an extension of that for big ellipticals (Model VII), higher scatter is predicted for low-mass galaxies.

Given that Model V reproduces the observed \( \bar{R} – M \) and \( \sigma_R \) relations, it is interesting to look at other predictions of the model. In this case, the bulge/disc ratio depends on the mass of the halo. A larger halo mass gives a larger value of \( m_B \) and, in the disc-instability model, this implies a larger bulge fraction. Hence we expect \( B/D \) to increase with galaxy mass. Fig. 16 shows the mean \( B/D \) ratio as a function of \( M \) according to Model V. The predicted trend is consistent with the observed correlation between \( B/D \) and galaxy mass (e.g. Roberts & Haynes 1994).

The formation of the bulge depends on the properties of the disc in the disc-instability-driven scenario. The bulge fraction (\( B/T \equiv m_B/m_T \)) should therefore be correlated with disc size. In Fig. 17, we show disc size as a function of \( B/T \) for a number of randomly selected Model V galaxies. The points of different type represent galaxies of differing stellar masses; open triangles, open squares, solid triangles and solid squares represent galaxies with masses from \( 10^8 \, M_\odot \) to \( 10^9 \, M_\odot \) respectively. The rough separation of galaxies according to mass is delineated by the solid lines in the figure. On average, galaxies with larger \( B/T \) ratios have larger discs. This is mainly due to the positive correlation between \( B/T \) and galaxy mass. For a given stellar mass, galaxies with large \( B/T \) ratios have smaller discs. This is consistent with the observational results of de Jong (1996). If the bulge/disc ratio is assumed to be random, as in Models I and II, disc size is independent of \( B/T \).

### 4.2 Early-type galaxies

Currently the most appealing model for the formation of elliptical galaxies assumes that they result from the merging of smaller systems. Numerical simulations have shown that mergers of disc galaxies of similar mass do indeed produce remnants resembling elliptical galaxies (e.g. Negroponte & White 1983; Hernquist 1992). However, it seems unlikely that every elliptical is the remnant of a merger between two similar spirals drawn from the observed local population. On the one hand, the stellar population of early-type galaxies is found to be so old that the typical star formation epoch must be at \( z > 2 \) (e.g. Bernardi et al. 1998; Thomas, Maraston & Bender 2002; Bernardi et al. 2003). On the other hand, detailed modelling of the merger histories of galaxies in a cold dark matter (CDM) universe suggests that each elliptical obtains its stars from progenitors covering a wide range in stellar mass, that the effective number of progenitors increases weakly with the mass of the elliptical, that the last major merging event is typically around redshift unity but with a wide dispersion, and that the progenitors may have been gas-rich, producing a substantial fraction of the observed stars during merger events (Baugh et al. 1996; Kauffmann 1996; Kauffmann & Charlot 1998; Kauffmann & Haehnelt 2000). Rather than treating the detailed merger statistics of CDM models, we here contrast two simpler models, one where ellipticals are built up by random mergers within a pool of initially small progenitors, and the other where they form through a single merger of a pair of similar ‘spirals’. As we will see, these pictures predict rather different size–mass relations for the resulting population. Consider two galaxies with stellar masses \( M_1 \) and \( M_2 \), and corresponding half-mass radii

---

**Figure 16.** The prediction of Model V for the average bulge/disc ratios for galaxies with different stellar masses.

**Figure 17.** The prediction of Model V for the relation between disc scale-length and bulge/total mass ratio for late-type galaxies. The points with different symbols represent galaxies in different mass ranges (as shown by the solid lines).
where \( f_{\text{orb}} \) is a parameter that encodes the amount of energy transferred from the stellar components of the two galaxies to the surrounding dark matter as they spiral together. The form of this term is a simple model suggested by the expected asymptotic scalings (see Cole et al. 2000), but unfortunately the appropriate value of \( f_{\text{orb}} \) depends on the details of the merging process. If we assume the galaxies to have no dark haloes and to merge from a parabolic orbit, then \( f_{\text{orb}} = 0.25 \) for an exponential disc, \( f_{\text{orb}} \approx 0.2 \) for a Hernquist (1990) profile and \( f_{\text{orb}} \approx 0.1 \) for a Freeman disc. If \( R < 0.25 \), the observed relation may be that typical merger epochs are later for more massive systems. Since disc galaxies are predicted to be larger and lower density at later times (e.g. MMW; Mao, Mo & White 1998), this results in a steepening of the predicted dependence of \( M \) on \( M_1 \). From the scaling laws of MMW it easy to show that the typical cosmic time at which merging occurs has to increase with elliptical mass roughly as \( t \propto M^{0.4} \) to reproduce the observed scaling of size with mass. This slow dependence is perhaps compatible with the expected dependence of formation time on halo mass in hierarchical cosmologies (Lacey & Cole 1993).

\[ \frac{M^2}{R} = \frac{M_1^2}{R_1} + \frac{M_2^2}{R_2} + f_{\text{orb}} \frac{M_1M_2}{R_1 + R_2}, \]  

(36)

For comparison, we have considered another model in which early-type galaxies are produced by a single major merger between two present-day spirals. We define a major merger to be one where the mass ratio of the progenitors is larger than 1/3. We use the observed late-type galaxy population as progenitors, and randomly merge two of them to form an early-type galaxy with size given by equation (36). Here again \( f_{\text{orb}} \) is assumed to have a normal distribution with mean 1.5 and dispersion 1.35. The results for \( R \) and \( M \) are shown as the dotted lines in Fig. 18. In this case, \( R \) is predicted to scale with \( M \) in the same way as for the progenitors. This conflicts with the observational results for early-type galaxies. A possible resolution may be that typical merger epochs are later for more massive systems. Since disc galaxies are predicted to be larger and lower density at later times (e.g. MMW; Mao, Mo & White 1998), this results in a steepening of the predicted dependence of \( R \) on \( M \). From the scaling laws of MMW it easy to show that the typical cosmic time at which merging occurs has to increase with elliptical mass roughly as \( t \propto M^{0.4} \) to reproduce the observed scaling of size with mass. This slow dependence is perhaps compatible with the expected dependence of formation time on halo mass in hierarchical cosmologies (Lacey & Cole 1993).

5 DISCUSSION AND SUMMARY

In this paper, we use a sample of 140 000 galaxies from the SDSS to study the size distribution of galaxies and its dependence on the luminosity, stellar mass and morphological type of galaxies. This data base provides statistics of unprecedented accuracy. These confirm a number of previously known trends, for example, the approximately constant surface brightness of luminous late-type galaxies (the ‘Freeman disc’), the Kormendy relations between surface brightness and luminosity for ellipticals, and a roughly log-normal
form for the size distribution function at fixed luminosity. We are able to quantify these properties, and to show other relations that cannot be seen in smaller samples. We find that, for late-type galaxies, there is a characteristic luminosity at $M_{V} = -20.5$ (assuming $h = 0.7$) corresponding to a stellar mass $M* \sim 10^{10.6}$ $M_{\odot}$. Galaxies more massive than $M_{0}$ have median size $\bar{R} \propto M^{0.3}$ and have dispersion in the size distribution $\sigma_{ln R} \sim 0.3$. For less massive galaxies, $\bar{R} \propto M^{0.15}$ and $\sigma_{ln R} \sim 0.5$. The $\bar{R}$--$M$ relation is significantly steeper for early-type galaxies, with $\bar{R} \propto M^{-0.55}$, but the $\sigma_{ln R}$--$M$ relation is similar to that of late-type galaxies. Fainter than $M_{0}$, the properties of red galaxies are not a simple extrapolation of the relations for bright early-type systems. These faint galaxies have low concentrations and their half-light radii are almost independent of luminosity. Brighter than $M_{0}$, the mean surface brightness of early-type galaxies also declines, so that systems near $M_{0} = -20$ have the highest values. In contrast, the average surface mass densities of early-type galaxies are independent of luminosity above $M_{0} = -20$.

We use simple theoretical models to understand the implications of our observational results for galaxy formation. We find that the observed $\bar{R}$--$M$ relation for late-type galaxies can be explained if the material in a galaxy has specific angular momentum similar to that of its halo, and if the fraction of baryons that form stars is similar to that in standard feedback models based on galactic winds. A successful model for the observed $\sigma_{ln R}$--$M$ relation also requires the bulge/disc mass ratio to be larger in haloes of lower angular momentum and the bulge material to transfer part of its angular momentum to the disc component. We show that this can be achieved if the amount of material that forms a galactic bulge is such that the disc component is marginally stable.

For early-type galaxies, the observed $\bar{R}$--$M$ relation is inconsistent with the assumption that they are the remnants of major mergers of present-day discs. It may be consistent with a model where the major mergers that formed lower-mass ellipticals occurred at earlier times and so involved more compact discs. The observed relation is consistent with a model where early-type galaxies are the remnants of repeated mergers, provided that the progenitors have properties similar to those of faint ellipticals and that the orbital binding energy is significant when two galaxies merge.

A number of issues remain unresolved in the present study. First, the photometric errors of the half-light radii are not considered in our analysis, which would finally enter into the derived dispersions of the size distribution. Unfortunately, an accurate assessment of error is difficult to make. To test how significant this effect can be, we have done Monte Carlo simulations including artificial errors in the measurements of the sizes. We found that, if the measurement errors are less than 10 per cent (assuming a Gaussian distribution), the effect on the derived width of the size distribution is negligible. Another uncertainty is connected to the fact that our galaxy sample covers a non-negligible range in redshift while galaxy sizes are based on half-light radii in a fixed band in the observational frame rather than in a fixed band in the rest frame. However, this effect should be quite weak because the sizes of galaxies are quite independent of the wavelength as we have found (see also Bernardi et al. 2003b). Yet another uncertainty may be caused by luminosity evolution of galaxies, which may affect the derived $R$--$L$ relation (see e.g. Schade et al. 1996; Schade, Barrientos & Lopez-Cruz 1997; Bernardi et al. 2003b). This effect should not be large in our results, since most of our galaxies are located in a relatively narrow redshift range ($0.05 < z < 0.15$). As a check, we have analysed a sample that only includes galaxies with redshift $z < 0.1$ and found negligible change in any of our results. Finally, since faint ellipticals have light profiles similar to those of disc galaxies, type classifications based on concentrations and profile indices miss these objects. Classifying according to colour suggests that these galaxies may have properties different both from massive early-type galaxies and from spiral galaxies, but it is unclear if all faint red galaxies in our samples are ellipticals. To resolve this issue, we need a more accurate indicator of morphological type. One way forward is to carry out disc/bulge decompositions for a large number of galaxies. Such work is under way in the SDSS Collaboration. With such decompositions, we can study the properties of the disc and bulge components separately, and so answer questions such as whether bulges have similar properties to elliptical galaxies of the same luminosity.
