ABSTRACT

We investigate non-linear scaling relations for two-dimensional (2D) gravitational collapse in an expanding background using a 2D TreePM code, and study the strongly non-linear regime ($\bar{\xi} \leq 200$) for power-law models. Evolution of these models is found to be scale invariant in all our simulations. We find that the stable clustering limit is not reached, but there is a model independent non-linear scaling relation in the asymptotic regime. This confirms results from an earlier study that only probed the mildly non-linear regime ($\bar{\xi} \leq 40$). The correlation function in the extremely non-linear regime is a less steep function of scale than reported in earlier studies. We show that this is due to coherent transverse motions in massive haloes. We also study density profiles, and find that the scatter in the inner and outer slopes is large and that there is no single universal profile that fits all cases. We find that the difference in typical density profiles for different models is smaller than expected from similarity solutions for halo profiles, and transverse motions induced by substructure are a likely reason for this difference being small.

Key words: gravitation – cosmology: theory – dark matter – large-scale structure of Universe.

1 INTRODUCTION

Large-scale structures such as clusters of galaxies are very overdense compared with the average density of the universe. It is believed that these were formed by the growth of small perturbations via gravitational instability (Peebles 1980; Peacock 1999; Bernardeau et al. 2002; Padmanabhan 2002b). In general, the equations that describe the growth of density perturbations due to gravitational clustering (Peebles 1974, 1980) cannot be solved analytically when the overdensities are large and one has to rely on N-body simulations for detailed predictions. Limited information about non-linear gravitational clustering can be obtained by using approximations or Ansätze, e.g. stable clustering (Peebles 1980) for which it is assumed that the infall velocity and Hubble velocity compensate for each other leading to a stable configuration. Stable clustering allows us to relate the initial spectrum of fluctuations with the final asymptotic spectrum of fluctuations (Davis & Peebles 1977). Non-linear scaling relations are a more detailed prescription for relating the initial and final spectrum of fluctuations (Hamilton et al. 1991). The motivation for studying non-linear scaling relations is to understand key phases in gravitational clustering and to identify the relevant process in each phase (Padmanabhan 1996).

Existence of non-linear scaling relations implies that gravitational clustering does not erase memory of initial conditions. This provides another useful and a more prosaic motivation for studying scaling relations, namely to be able to make predictions about clustering of galaxies for a given power spectrum (Hamilton et al. 1991). Scaling relations can also be used to make predictions for weak lensing observations in a given model (Kaiser 1992; Jain & Seljak 1997). These scaling relations are valid for hierarchical models where the initial conditions contain fluctuations at all scales and the amplitude of fluctuations increases monotonically as we go from large scales to small scales.

Non-linear scaling relations indicate that there are three prominent regimes in evolution of gravitational clustering. When the amplitude of perturbations is small so that the density contrast ($\delta = \rho / \bar{\rho} - 1$) is close to zero ($|\delta| \ll 1$), mode coupling is not important and the evolution closely follows the predictions of linear perturbation theory (Peebles 1974). The power spectrum and correlation function evolve without a change in shape in the linear regime. As the density contrast grows and becomes comparable to unity, motions induced by gravitational collapse start to dominate over the expansion of the universe. The quasi-linear regime is dominated by infall on to density peaks and the correlation function grows
rapidly in this phase (Padmanabhan 1996). Gravitational collapse leads to formation of structures in or close to dynamical equilibrium and further evolution of density contrast is dominated by depletion of average density due to expansion of the universe as the density of collapsed structures remains almost constant. We shall call this the asymptotic regime.

Initial conditions with power-law power spectra are very useful for such studies. These power spectra have the form $P(k) \propto k^n$ with $n$ being the index of the power spectrum. We require $(n + D) > 0$ for hierarchical clustering and $N$-body simulations can be used for only these types of models, indeed even for these models there are restrictions on the size of the simulation box in order for the simulation to reproduce the model correctly (Bagla & Ray 2005). Here, $D$ is the number of spatial dimensions in which gravitational clustering is being studied. If we consider an Einstein–de Sitter universe then such a model is characterized by the scale of non-linearity $r_{NL}$ and the index $n$, where $r_{NL}$ is defined as the scale at which rms fluctuations in linearly extrapolated density contrast $[\sigma_L(r)]$ is unity:

$$\sigma_L^2(r) = a^2 r^{-n + D},$$

$$r_{NL} = a^{2/(n + D)}.$$  

(1)

If the evolution of clustering is self-similar then the non-linear correlation function plotted as a function of $r/r_{NL}$ should have the same shape at all epochs for a given index $n$. Note that the evolution is expected to be self-similar if $r_{NL}$ is the only scale in the problem and it is not expected in cosmologies with non-zero spatial curvature or a non-power-law expansion factor.

Several studies have attempted to understand the nature of the asymptotic regime, mainly with help of $N$-body simulations (Peacock & Dodds 1994; Jain et al. 1995; Colombi, Bouchet & Hernquist 1996; Padmanabhan et al. 1996; Peacock & Dodds 1996; Jain 1997; Kanekar 2000; Jing 2001; Smith et al. 2003). Key conclusions of these studies about the asymptotic regime may be summarized as follows.

(i) Stable clustering is not reached in the range of non-linearities explored by $N$-body simulations. However, the departure from stable clustering for most models is small.

(ii) Gravitational clustering does not erase memory of initial conditions, i.e. the non-linear power spectrum is not independent of the linear power spectrum to the extent it could be probed. There is no universal asymptotic regime.

One of the reasons for the inability to resolve the problem of asymptotic regime has been the limited dynamic range of $N$-body simulations. The problem of dynamic range can be circumvented by simulating a two-dimensional (2D) system (Bouchet, Adam & Pellat 1985; Engineer, Srinivasan & Padmanabhan 1999; Padmanabhan & Kanekar 2000) instead of a three-dimensional (3D) one, wherein a much higher dynamic range can be achieved with similar computational resources (Bagla et al. 1998; Munshi et al. 1998). Generic features like non-linear scaling relations are likely to be independent of dimension and, in fact, the scaling relations in the quasi-linear regime were predicted (Padmanabhan 1996) well before these could be tested in simulations (Bagla et al. 1998). If we can understand the nature of the asymptotic regime in two dimensions, it will help us solve the problem in three dimensions even if we cannot map the solution directly to the full problem in three dimensions. Previous studies of gravitational clustering in two dimensions concluded that there is no stable clustering (Bagla et al. 1998; Munshi et al. 1998). Both the studies mentioned above were limited to $\xi \leq 40$ and the dynamic range in the non-linear regime was limited compared with the present study (see equation 6 for the definition of $\xi$). In this work, we revisit the same issues, but using the 2D TreePM code (Ray 2004) for $N$-body simulations. The TreePM code has a better force resolution as compared with a particle mesh (PM) code (Bouchet et al. 1985), therefore in our simulations we have a significantly larger dynamic range over which we can study the asymptotic regime.

A related issue is that of density profiles of haloes surrounding galaxies and clusters. Non-linear scaling relations in the asymptotic regime depend on the kind of dynamical equilibrium that is reached in massive haloes, if an equilibrium is ever reached. Under the assumption of self-similar collapse, the density profiles of massive haloes can be related to the initial conditions and also to the dynamics within these haloes (Fillmore & Goldreich 1984; Subramanian 2000). If these models are true then the slope of the density profile at small scales is related to the index of the power spectrum as:

$$\rho(r) \propto r^{-\eta}, \quad \eta = \frac{D(n + D + 1)}{2 + D + n}.$$  

(2)

If self-similar collapse of haloes is the correct description then the final density profile of a halo carries information about the initial profile and hence about the power spectrum (Bardeen et al. 1986). It has been claimed that gravitational clustering in hierarchical models leads to a universal density profile (Navarro, Frenk & White 1996) irrespective of the initial conditions. We shall refer to this density profile as the NFW profile:

$$\frac{1}{\rho_{SW}(r)} \propto \frac{1}{(r/r_s)(1 + r/r_s)^2}. $$  

(3)

Here, $r_s$ is a scale radius. We will also use the term $r_{200}$ for this. This profile is characterized by a $r^{-3}$ decline at large radii and a cuspy inner profile of the form $\rho(r) \propto 1/r$. The claim of universality has been tested in several studies (Cole & Lacey 1996; Navarro et al. 1996; Fukugishe & Makino 1997; Tormen, Bouchet & White 1997; Kravtsov et al. 1998; Moore et al. 1998; Ghigna et al. 2000; Subramanian, Cen & Ostriker 2000; Klypin et al. 2001; Power et al. 2003; Fukugishe, Kawai & Makino 2004; Navarro et al. 2004) and, though there are disagreements, it appears that the NFW profile is consistent with the density profiles of massive haloes in $N$-body simulations even if it is not the best fit. This essentially implies that there is a scatter in density profiles and one can fit different functional forms to the $N$-body data (Jing 2000; Bullock et al. 2001).

If true, the existence of NFW-like profile implies that there are some universal aspects of gravitational clustering in an expanding universe. There is no ab initio derivation of the NFW profile, but one can argue that if there is a universal profile it should have same asymptotes as the form shown above (Syer & White 1998; Nusser & Sheth 1999; Padmanabhan 2002a).

We briefly review non-linear scaling relations in the following section. Numerical simulations used in the present work are discussed in Section 3. We conclude in Section 4.

2 NON-LINEAR SCALING RELATIONS

In this section, we review the non-linear scaling relations for gravitational clustering in two dimensions. The non-linear and the linear correlation functions at two different scales can be related by non-linear scaling relations (Hamilton et al. 1991; Nityananda & Padmanabhan 1994). The relation between these scales is given by the characteristics of the pair conservation equation (Peebles 1980; Nityananda & Padmanabhan 1994) under the assumption that the pair velocity function $h$ (see below) depends on $r$ and $t$ through $\xi$. 

In such a case, or for any value of expansion balance each other in structures in dynamical equilibrium. According to Goldreich & Goldreich (1984) imply that for collapse of cylindrical perturbations in non-linear scaling relations. The self-similar models (Fillmore & Goldreich 1984) imply that for collapse of cylindrical perturbations in an orthogonal plane. Particles in the N-body simulation represent the intersection of these needles with this plane and the force of interaction between ‘particles’ is given by the solution of the Poisson equation in two dimensions. The interparticle force falls as 1/r, unlike the inverse square force in three dimensions.

We use the 2D TreePM code (Ray 2001), a modified version of the 3D TreePM code (Bagla 1999). The TreePM code splits the interaction force into two parts, the long-range force is computed in Fourier space and the short-range component is computed in real space. The TreePM code does not use the usual PM force as the long-range force: this allows us to control errors in force over the entire range of scales (Bagla 2003; Bagla & Ray 2003; Ray 2004).

We soften the 2D gravitational force at small scales in order to ensure collisionless evolution of the particle distribution in our simulations. The problem of the particle distribution in the system completely as the ultimate goal is to carry over the understanding to 3D systems. Therefore, we study the evolution of 2D perturbations in a 3D expanding universe (Fillmore & Goldreich 1984). We start with a set of infinitely long straight ‘needles’ all pointing along one axis. The evolution keeps the needles pointed in the same direction and we study gravitational clustering of these needles in an orthogonal plane. Particles in the N-body simulation represent the intersection of these needles with this plane and the force of interaction between ‘particles’ is given by the solution of the Poisson equation in two dimensions. The interparticle force falls as 1/r, unlike the inverse square force in three dimensions.

We use the 2D TreePM code (Ray 2004), a modified version of the 3D TreePM code (Bagla 2002; Bagla & Ray 2003). This code splits the interaction force into two parts, the long-range force is computed in Fourier space and the short-range component is computed in real space. The TreePM code does not use the usual PM force as the long-range force: this allows us to control errors in force over the entire range of scales (Bagla 2002; Bagla & Ray 2003; Ray 2004).

We soften the 2D gravitational force at small scales in order to ensure collisionless evolution of the particle distribution in our simulations. We use a cubic spline form for softening, i.e. each particle is assumed to have an extended mass distribution represented by the normalized spline kernel used in the smoothed particle hydrodynamics (SPH) formalism (Monaghan 1992). This softens the force at scales smaller than the softening length e and at scales larger than e we get the full 1/r force. All N-body simulations reported in this paper used e ≥ 0.2 in units of the average interparticle separation.

We have carried out a series of numerical simulations with power-law initial spectra with indices n = −0.4, 0.0 and 1.0. Several realizations of each power spectrum were simulated. Scatter in values across this suite of simulations was used to estimate the error bars. It is difficult to reach the asymptotic regime for n < −0.4 before the perturbations at the box scale become important and hence we have not used models with a more negative index. Models were normalized so that \( \Delta^2(k = 8\pi, a = 1) = 1 \) where \( \Delta \) is the wave number of the fundamental mode, essentially the fluctuations at 1/8 of the box size were normalized to unity at a = 1. Simulations were run up to a sufficiently late epoch while requiring that the fluctuations at half the box scale were well within the linear regime at the final epoch, i.e. \( \Delta^2(k = 2k_\rho, a_{\text{fin}}) \ll 1 \).

Simulations discussed here used 2048^2 particles on a 2048^2 grid in an Einstein–de Sitter background universe. TreePM code was used for all the simulations, though we have checked many of the results in larger 4096^2 PM simulations. We used \( r_\rho = 1.0 \) grid length in the TreePM code: this is the scale used for dividing the force into a short-range and a long-range component (Bagla 2002; Bagla & Ray 2003; Ray 2004). Error in force depends largely on the choice of this scale and the cell opening criterion; we use \( \theta_c = 0.5 \).

In an Einstein–de Sitter universe, the evolution of perturbations with a power-law power spectrum is expected to be scale invariant. The only scale introduced by gravitational clustering is the scale of non-linearity \( r_{\text{NL}} \).

We outline the key results of these simulation studies in the following subsections.

### 3.1 Correlation function

We find that the evolution of the system is self-similar in that all the relevant quantities have the same form when scaled by

\[ \xi(x) = x^{-2(\alpha n + 2)}/[\alpha + (n + 2)], \]

where \( \xi \) is the correlation function. The characteristics of this equation are \( x^2[1 + \xi(x, a)] = l^2 \), where \( x \) and \( l \) are the two scales used in non-linear scaling relations. The self-similar models (Fillmore & Goldreich 1984) imply that for collapse of cylindrical perturbations in the initial density contrast inside that shell are related as \( x_\rho \propto l/\delta \propto 1/\xi(L) \). Here, \( \xi \) is the linearly extrapolated mean correlation function. Noting that in two dimensions mass enclosed in a shell \( M \propto x^2 \), we find \( \xi(x) \propto [\xi(l)]^2 \) in the regime dominated by infall. Thus, in 2D the scaling relations are:

\[ \xi(x) = 2x^{-2} \int x \xi(r) dr, \]

where \( \xi \) is the correlation function. The characteristics of this equation are \( x^2[1 + \xi(x, a)] = l^2 \), where \( x \) and \( l \) are the two scales used in non-linear scaling relations. The self-similar models (Fillmore & Goldreich 1984) imply that for collapse of cylindrical perturbations in the initial density contrast inside that shell are related as \( x_\rho \propto l/\delta \propto 1/\xi(L) \). Here, \( \xi \) is the linearly extrapolated mean correlation function. Noting that in two dimensions mass enclosed in a shell \( M \propto x^2 \), we find \( \xi(x) \propto [\xi(l)]^2 \) in the regime dominated by infall. Thus, in 2D the scaling relations are:
Gravitational collapse in an expanding universe

1998) favoured $h \approx 0.75$ and the other found $h(n + 2) = 1.3$ (Munshi et al. 1998). The latter behaviour erases memory of initial conditions and the slope of the correlation function in the asymptotic regime is the same for all models. The dynamic range in both the studies was limited to $\xi \sim 10$.

The current work with a higher dynamic range agrees with the slope for $h = 0.75$ in the region of overlap with the previous work (Bagla et al. 1998) and rules out the possibility of $h(n + 2) = 1.3$. The dashed line with the expected slope for $h = 0.75$ is marked in Fig. 1 and it runs parallel to the curve up to approximately $\xi \approx 40$, the largest non-linearity studied earlier (Bagla et al. 1998). As clustering increases, the slope of the correlation function decreases below the slope expected for $h = 0.75$. Slope of the correlation function for these two models is shown in Fig. 2. The asymptotic slope of the correlation function is $-0.53 \leq \gamma \leq -0.50$ for $n = -0.4$ and $-0.80 \leq \gamma \leq -0.77$ for $n = 1$, where $\gamma = \partial \log \xi / \partial \log r$ and is evaluated at $\xi \geq 100$. We have given the 95 per cent confidence limits for the slope; the limits were derived using a $\chi^2$ fit to the correlation function in the asymptotic regime. Different values of $\gamma$ imply departure from the $h(n + 2) = \text{constant}$ asymptote. The values of $\gamma$ listed above are consistent with $0.416 \leq h \leq 0.451$ for $n = -0.4$ and $0.417 \leq h \leq 0.444$ for $n = 1$. Thus, we recover a similar range of asymptotic values for $h$ from the correlation function. As we will show in Section 3.2, the slope of the correlation function is a more stable estimator of $h$ than a direct determination.

Fig. 2 shows the non-linear scaling relations. $\xi(x, a)$ is plotted as a function of $\xi(x, a)$ for $n = -0.4$, 0 and 1. Data from multiple epochs have been used here. Curves marking the linear, quasi-linear and asymptotic regimes are shown here. We have also marked a line showing the stable clustering limit. The equations for the piecewise fit are:

$$\xi(x, a) = \begin{cases} 
\xi_{nl}(a, l), & 0.5 \leq \xi(x) \leq 8; \\
2 \xi_{nl}(a, l)^2, & 5 \leq \xi(x) \leq 10; \\
10.5 \xi_{nl}(a, l)^{0.45}, & 10 \leq \xi(x).
\end{cases}$$

(9)

It is remarkable that the points for all the three models follow the same non-linear scaling relation. The asymptotic slope implied by the scaling relation lies near $h = 0.45$, but it is difficult to say whether this is the final value or if this continues to decrease as we go to higher non-linearities. This evolution is inconsistent with the asymptote of $h(n + 2) = \text{constant}$, as the scaling relations for different models would have been different in that case.

The results shown here with the TreePM code match with the correlation function obtained in 4096$^3$ PM simulations. This comparison has been carried out up to $\xi \leq 70$.

### 3.2 Pair velocity

Fig. 3 shows the pair velocity $h(r, a)$ as a function of $\xi(r, a)$ for a large number of epochs $a$ for $n = -0.4$ (upper panel) and $n = 1$. The dashed line shows the expected value of $h$ in the linear limit. For the linear and quasi-linear regime ($\xi \leq 10$), $h$ is a single valued function of $\xi$, irrespective of the epoch for a given model. Indeed, we find that there is no significant difference between the curves for different models at $\xi \leq 10$ and at higher non-linearities there is a large scatter in the curves so it is difficult to test any claims using Fig. 3. Thus, simulations are consistent with the Ansatz that $h$ depends on epoch and scale through $\xi$ (Nityananda & Padmanabhan 1994) and this allows us to find the form of the non-linear scaling relation. We can certainly do this for a given model and, as we do not find significant differences between
Figure 2. The upper panel shows the non-linear scaling relation. $\xi(x, a)$ is plotted as a function of $\tilde{\xi}(l, a)$ for $n = -0.4, 0$ and 1. Data from multiple epochs have been used here. Curves marking the linear (thick curve), quasi-linear (dashed curve) and asymptotic regime (dot-dashed curve) are shown here. We have also marked a dotted line showing the stable clustering limit.

A remarkable feature of clustering in two dimensions is that the non-linear correlation function in the asymptotic regime is smaller than the linear correlation function. The slope $\gamma$ is shown as a function of $\tilde{\xi}(x, a)$ in the lower panel. Circles mark the slope for the $n = 1$ model and plus signs mark the slope for the $n = -0.4$ model. Points for the $n = 1$ model are displaced upwards by 2 for clarity.

by Fig. 4 where $h$ determined directly is compared with values obtained from the non-linear scaling relation.

The value of $h$ fluctuates a lot at late epochs; we mentioned in the previous section that the slope of the correlation function gives a more stable estimate of $h$. As a result of this, some of the late epochs used in Fig. 1 have not been plotted in Fig. 3. The key feature in this regime is that $h < 1$ and it does not show any sign of heading towards the stable clustering limit of $h = 1$. This is consistent with the results from the slope of the correlation function.

It is important to understand what $h < 1$ means in terms of dynamics. One possibility is that the haloes are evaporating. This can happen if two-body relaxation is important; but we have used different models, there does not seem to be any power spectrum dependence in scaling relations. However, there will be a dependence on cosmology (Padmanabhan et al. 1996). Conversely, non-linear scaling relations can be used to find $h(\tilde{\xi})$.

We have checked that the scaling relations plotted in Fig. 2 are consistent with the $h(\tilde{\xi})$ curves plotted in Fig. 3. This is demonstrated by Fig. 4 where $h$ determined directly is compared with values obtained from the non-linear scaling relation.

The value of $h$ fluctuates a lot at late epochs; we mentioned in the previous section that the slope of the correlation function gives a more stable estimate of $h$. As a result of this, some of the late epochs used in Fig. 1 have not been plotted in Fig. 3. The key feature in this regime is that $h < 1$ and it does not show any sign of heading towards the stable clustering limit of $h = 1$. This is consistent with the results from the slope of the correlation function.

It is important to understand what $h < 1$ means in terms of dynamics. One possibility is that the haloes are evaporating. This can happen if two-body relaxation is important; but we have used
Gravitational collapse in an expanding universe

Figure 4. The pair velocity $h(r, a)$ is plotted as a function of $\bar{\xi}(r, a)$ at late times for $n = -0.4$. Error bars are also shown here. The range of $h(r, a)$ expected from equation (4) is shown here using dashed lines. The expected values and the directly measured values of $h$ are consistent within the error bars for nearly the entire range of scales.

$\epsilon \geq 0.2$ grid lengths in all our simulations and the number density of particles in most haloes is very high. Hence, two-body scattering should not be important. A poor integrator for the equation of motion can also lead to the evaporation of haloes. We have tested the integrator in three-body problems and with highly eccentric binary orbits to ensure that the problem does not lie with incorrect evolution of trajectories.

In order to probe the dynamics further, we also study non-radial motions. Analogous to $h$, the radial component of the pair velocity scaled by the Hubble velocity, we define the transverse pair velocity function as

$$g(r, a) = \frac{|v_{p_x} - v_{p_y}|}{Hr^2}. \quad (10)$$

Here, the angle brackets denote averaging over all pairs with separation $r$, $v_p$ is the pair velocity (peculiar velocity) and $r_p$ is the separation of the pair of particles. $H$ is the Hubble parameter. The equivalent object in three dimensions is

$$g(r, a) = |g| = \frac{|\mathbf{v} \times \mathbf{r}|}{Hr^2}. \quad (11)$$

In two dimensions, the ‘cross’ product of two vectors is just a number. Fig. 5 shows $|g|$ as a function of $\bar{\xi}$. We have plotted the magnitude of $g(r, a)$ as its value oscillates about zero at large scales. This curve is plotted for only one epoch but the relative value of $|g|$ compared to $h$ shows that this is a significant component. Note that we require coherent transverse motions in order to detect anything here, as random transverse motions will cancel out in the sum. We do not find any systematic excess in pairwise transverse velocity dispersion as compared to the pairwise collinear velocity dispersion. In dynamical equilibrium, these should have the same magnitude in two dimensions and at $\bar{\xi} \gg 10$ we find this to be true.

To investigate this further, we have studied motions in individual haloes by plotting the angular momentum profile as a function of distance from the centre of the halo. There are no systematic features of shape worth commenting except that for most haloes there are annuli with coherent rotation. Note that this does not imply a coherent rotation for the halo as the direction of rotation reverses a few times. Fig. 6 shows the circularly averaged angular momentum of particles in a halo within a distance $r$ from the centre of mass of the halo for some (randomly selected) haloes. The upper panel is for index $n = -0.4$ and the lower for $n = 1.0$. Clearly, all the haloes in both panels have annuli with coherent rotation. In some cases, angular momentum contributed by adjacent annuli is in the opposite direction. The net angular momentum in these haloes contributes a small fraction of the kinetic energy of particles in these haloes. A
some haloes. Distance is certainly more substructure in the early phase can generate such transverse motions (Bagla, Prasad & Ray 2005) and there is certainly more substructure in the $n = 1$ model. We put forward the hypothesis that collisions between substructure are responsible for the generation of coherent transverse motions. We are testing this hypothesis in a series of numerical simulations. Results of these studies will be reported elsewhere.

3.3 Density profiles of massive haloes

Density profiles of massive haloes and non-linear scaling relations are closely related. Density profiles of very massive haloes are easier to study as these extend over a large region, large compared with the softening length, which is the smallest scale we can resolve in our simulations. We identified haloes in our simulations using the method of density peaks (Tormen et al. 1997). In this method, the density field is smoothed at a large length-scale $R = 5$ grid lengths and peaks in the smoothed density field are identified. Particles within a distance $R$ of a peak are selected and we find the centre of mass for these particles. We now select a smaller set of particles out of these, those that are within $R - \Delta R$ from the centre of mass, and compute the centre of mass. These iterations continue till we are left with only a small number of particles, say about 100. The final centre of mass is taken to be the centre of the halo and the density profiles are plotted as a function of distance from this centre. We apply two further criteria, which are as follows.

(i) Central density contrast of the halo must be very large, $\delta \geq 500$.

(ii) Haloes and their neighbourhood should be smooth and there should be no major merger going on. To implement this in an objective manner, we compute the ratio $\chi = (\cos^2 \phi)/ (\sin^2 \phi)$ where the average is over all particles within the central region of the halo and $\phi$ is the position angle of a particle from the centre of mass. We require $0.9 \geq \chi \geq 1.1$ for a halo to be used for density profiles.

These two criteria reject approximately 75 per cent of all the haloes with rejection being more frequent for models with a larger index $n$.

Fig. 7 shows the density profiles of haloes that satisfy these criteria in our simulations. Density profiles of a large number of haloes are plotted; for each halo we have drawn density $\rho$ as a function of $r/r_{200}$, where $r_{200}$ is the scale at which the density is 200 times the average. Average density is unity in these simulations. It is clear that there is a large scatter in density profiles. The inner slope varies from 0.4 to 1.4 for $n = -0.4$, whereas it is in the range 0.6 to 1.6 for $n = 1$. The inner slope $\eta$ is obtained by fitting a power law that passes through $\rho = 200$ and $r/r_{200} = 1.0$ and only points inside of this radius are used. The distribution of the inner slope of density profiles is very broad, as is obvious from the range. The median $\eta$ is approximately 0.9 for $n = -0.4$ and 1.1 for $n = 1$. Self-similar, spherical collapse predicts an inner slope of $\eta = 0.89$ and 1.2 for $n = -0.4$ and 1, respectively (equation 2). These values are well within the scatter of inner slopes. Clearly, the answer lies in between the prediction for the self-similar collapse and a universal slope.

It is difficult to explain the large scatter seen in density profiles. The origin of scatter can lie in environmental dependence as well as in different formation histories for haloes. We can, however, address the issue of the small systematic shift in the median slope as compared with that expected from stable clustering.

Transverse motions can affect the density profile of massive haloes in a significant manner (Subramanian 2000). Such effects will be stronger if the transverse motions are stronger and, as is obvious from Fig. 5, transverse motions are stronger for larger $n$. Rotation is playing a more important role in models with more substructure and is leading to flatter density profiles. This reduces the
Gravitational collapse in an expanding universe

Spherically averaged density profiles of a number of spherically symmetric virialised haloes from simulations with indices $n = -0.4$ (upper panel) and $n = 1.0$ (lower panel). Density is plotted as a function of $r/r_{200}$. The four dashed lines in each panel mark the approximate extremes of inner ($\eta$) and outer ($\beta$) slopes for the density profiles. The smallest haloes have more than $10^3$ particles inside the virial radius and the largest haloes have more than $10^4$ particles. All the haloes in the figure were taken from TreePM simulations with 2048$^3$ particles.

The difference between density profiles of massive haloes for these models. This, we believe, is a common explanation for the non-linear scaling relations and density profiles.

3.4 Virial equilibrium

The stable clustering limit requires the formation of objects that are in dynamical equilibrium. Following Peebles (1980), we compute the second time derivative of the moment of inertia and set it to zero for a cluster of particles in dynamical equilibrium. This gives us the condition to be satisfied for dynamical equilibrium. We get

$$\sum_i \frac{1}{2} m_i r_i^2 = \frac{1}{2} \sum_i \sum_{j \neq i} G m_i m_j,$$

where the sums are over all particles and dots denote time derivatives. Particles are located at $r_i$ and have velocities $\dot{r}_i$, and $m_i$ is the mass of the $i$th particle. Thus, the kinetic energy depends only on the total mass of the halo. If the massive haloes that we are studying here are in virial equilibrium then the kinetic energy $T$ for these haloes should be proportional to $M^2$. For each halo used for density profiles, all particles within the radius $r_{200}$ were used to plot Fig. 8.

It is clear that these quantities are correlated even though there is a large scatter about the average relation. Thus, we may conclude that the massive haloes are close to dynamical equilibrium.

4 CONCLUSIONS

The basic motivation for this work was to improve our understanding of non-linear scaling relations for 2D gravitational clustering. Previous studies (Bagla et al. 1998; Munshi et al. 1998) established the behaviour for the quasi-linear regime, but could not probe the nature of the asymptotic regime. We used the 2D TreePM code (Ray 2004), which allows us to study the non-linear regime in far greater detail, as compared with the PM code used in earlier studies. The results of our study can be summarized as follows.

(i) The evolution of the correlation function for power-law models is scale invariant up to the highest non-linearities reached in our simulations.

(ii) We reproduce the results of earlier studies in the quasi-linear regime. We confirm that the slope of the non-linear scaling relation...
in this regime is close to 2, as predicted on the basis of the infall dominated growth model (Padmanabhan 1996).

(iii) We do not find any difference in the non-linear scaling relation for different power-law models. Thus, the information about initial conditions is retained even in the extremely non-linear regime.

(iv) The stable clustering limit \((h \rightarrow 1 \text{ as } \xi \rightarrow \infty)\) is not reached. [Though it is generally claimed that stable clustering with \(h \rightarrow 1\) is a natural asymptotic state, it has been shown that the Davis–Peebles scale-invariant solution (Davis & Peebles 1977) and the hierarchical model for the three-point function are inconsistent with the standard stable-clustering picture (Kanekar 2000). This, of course, is for gravitational collapse in three dimensions.] This can be concluded from the slope of the correlation function, pair velocity, as well as density profiles of massive haloes.

(v) Pair velocities in the asymptotic regime are smaller than expected from the stable clustering model. This does not imply that massive haloes are evaporating.

(vi) The transverse component of pair velocity is more significant for models with a larger spectral index, i.e. for models with more substructure. This suggests that gravitational collisions between substructure orbiting within haloes are responsible for generating coherent transverse motions.

(vii) We find that there is no universal density profile for massive haloes in 2D gravitational clustering. There is a large scatter in the inner as well as outer slopes of density profiles. The median value of the inner slope is different for different models, though the difference is much smaller than the scatter in values. Tests show that these clusters are close to dynamical equilibrium.

(viii) The difference in the median inner slope for different models is smaller than expected from self-similar spherical collapse. We argue that the difference in significance of transverse motions for different models is responsible for this change.

Many of the conclusions listed here have been checked independently in large PM simulations (4096^2 particles) up to \(\xi \leq 100\).

Further work is required to test our hypothesis that gravitational collisions between substructure are responsible for generating coherent transverse motions. We are carrying out a detailed study using numerical simulations where we tune the amount of substructure to test this proposal.

Considerable work has been done to study the non-linear scaling relations in three dimensions (Hamilton et al. 1991; Nityananda & Padmanabhan 1994; Peacock & Dodds 1994; Jain et al. 1995; Padmanabhan 1996; Padmanabhan et al. 1996; Peacock & Dodds 1996; Bagla et al. 1998; Smith et al. 2003). We intend to study these again in light of insight developed using tests in clustering in two dimensions. It has been shown that the scaling relations for gravitational clustering in three dimensions depend on the initial spectrum of fluctuations (Smith et al. 2003). It is important to understand the origin of this index dependence and test whether substructure plays a role in this. The transverse pair velocity function has been introduced in equation (10); we are studying the 3D equivalent of this quantity in order to probe the role of transverse motions in gravitational clustering in the full 3D problem. These studies should help us understand the non-linear scaling relations better.
