Earth’s middle age, extending from 1.7 to 0.75 Ga, was characterized by environmental, evolutionary, and lithospheric stability that contrasts with the dramatic changes in preceding and succeeding eras. The period is marked by a paucity of preserved passive margins, an absence of a significant Sr anomaly in the paleoseawater record and in the $e_{	ext{Sr}}$ record in detrital zircon, a lack of orogenic gold and volcanic-hosted massive sulfide deposits, and an absence of glacial deposits and iron formations. In contrast, anorthosites and kindred bodies are well developed and major pulses of Mo and Cu mineralization, including the world’s largest examples of these deposits, are features of this period. These trends are attributed to a relatively stable continental assembly that was initiated during assembly of the Nuna supercontinent by ca. 1.7 Ga and continued until breakup of its closely related successor, Rodinia, ca. 0.75 Ga. The overall low abundance of passive margins is consistent with a stable continental configuration, which also provided a framework for environmental and evolutionary stability. A series of convergent margin accretionary orogens developed along the edge of the supercontinent. Abundant anorthosites and related rocks developed inboard of the plate margin. Their temporal distribution appears to link with the secular cooling of the mantle, at which time the overlying continental lithosphere was strong enough to be thickened and to support the emplacement of large plutons into the crust, yet the underlying mantle was still warm enough to result in widespread melting of the lower thickened crust.

INTRODUCTION

Earth’s rock record is incomplete, with a heterogeneous distribution of rock units and events that correspond to periods of supercontinent assembly (Cawood et al., 2013). For example, U-Pb zircon crystallization ages (Voice et al., 2011), whether determined from igneous rocks or detrital sediments, and the age distribution of metamorphic rocks (Brown, 2007) show peaks in the frequency of occurrence at the time of supercontinent assembly (Bradley, 2011). The period 1.7–0.75 Ga, however, is anomalous (Fig. 1) in that it is characterized by the following.

1. A paucity of passive margins (Bradley, 2008), and notably no passive margin age peak corresponding with the phase of assembly of the Rodinia supercontinent as there is for the preceding Nuna and succeeding Gondwana cycles.

2. An absence of glacial deposits (Bradley, 2011) and iron formations (Bekker et al., 2010).

3. No significant Sr anomaly in the paleoseawater record (Shields, 2007) or in the $e_{	ext{Sr}}$ record in detrital zircon (Belousova et al., 2010).

4. A lack of phosphate deposits, even though they were well established ca. 2.2–1.8 Ga and after 0.75 Ga (Papineau, 2010), periods that also correspond with maxima in the geological record in black shale abundance and in the chemical index of alteration (Condie et al., 2001). Such patterns suggest major global changes in ocean and atmospheric chemistry in the Paleo- and Neoproterozoic, and perhaps more stable conditions in the intervening interval (cf. Brasier and Lindsay, 1998).

5. Relatively high ocean salinity before a significant decrease after 800 Ma in association with the development of major evaporate basins, possibly linked to increased sulfate delivery and development of S-rich porphyry deposits in the Phanerozoic (Richards and Mumin, 2013).

6. Massif-type anorthosites and kindred bodies, also variously termed A-type granite, anorogenic granite, anorthosite-mangerite-charnockite-granite suite, ferroan feldspathic granitoids, ilmenite-granite, or Rapakivi granites, are characteristic features of the Proterozoic, largely in the period 1.8–1.0 Ga (Ashwal, 2010).

7. Limited orogenic gold deposits between 1.7 and 0.9 Ga, accounting for significantly less than 1% of known production, yet corresponding to the generation of almost 20% of the preserved crustal record (Goldfarb et al., 2001). Volcanic-hosted massive sulfide (VHMS) deposits show a similar distribution (Huston et al., 2010). Sedimentary rock-hosted manganese deposits are also conspicuous by their absence between 1.8 and 0.8 Ga; Maynard (2010) suggested that this corresponds to the low frequency of black shale deposition and may relate to a monotonous low-oxygen ocean, with nonsulfidic deep water. Sedimentary rock–hosted stratiform copper deposits are largely absent from the rock record between 1.8 and 0.8 Ga (Hitzman et al., 2010).

PALEOGEOGRAPHIC CONFIGURATIONS

The pattern of rock units and the events outlined in Figure 1 indicate that the period from ca. 1.7 Ga to 0.75 Ga, herein termed Earth’s middle age, was unique with respect to preceding and succeeding eras of Earth history (cf. Holland, 2006). This period encompasses the proposed Rodinian supercontinent cycle (ca. 1.3–0.75 Ga) and part of the Nuna cycle (ca. 2.1–1.3 Ga). There is increasing evidence that the change from Nuna to Rodinia was one of transition in which Siberia, Laurentia, and Baltica formed a stable core that assembled during construction of Nuna by 1.8–1.7 Ga and continued, with little change in configuration, until Rodinia breakup at 0.75 Ga (e.g., Evans, 2013). This contrasts with the significant changes in continental configurations that occurred in the initial assembly of Nuna or in the transition from Rodinia breakup to Pangaea assembly. Extension-related magmatism at ca. 1.4–1.25 Ga is widespread around parts of Laurentia, Baltica, and Siberia and is ascribed to Nuna breakup (Evans, 2013). However, the general paucity of passive margins through the Mesoproterozoic (Fig. 1) and the absence of any evidence for 1.1–1.0 Ga orogenesis in blocks such as Siberia (Gladkochub et al., 2010) argue for no significant breakup and reassemly of these continental fragments in the transition from Nuna to Rodinia (cf. Bradley, 2008).

The overall stability in the configuration of the core components of Nuna and Rodinia is mimicked in the presence of a long-lived accretionary orogen that developed along the margins of Laurentia, Baltica, Australia, and Amazonia from ca. 1.8 Ga to 1.25 Ga (e.g., Whittenmyer and Karlstrom, 2007). Accretionary activity terminated with the 1.25–0.95 Ga Grenville orogeny and equivalent tectonothermal events leading to final assembly of Rodinia, which involved collision assembly of Amazonia, India, and related fragments onto the stable Nuna core. These events resulted in the 1.1–1.0 Ga peak in granulite and eclogite facies metamorphism (Fig. 1; Brown, 2007).

IMPLICATIONS

Rock units and events depicted in Figure 1 span surficial (atmosphere, oceans, biosphere) and deep Earth (lithospheric) proxies, and their temporal equivalence suggests that they are linked and therefore controlled through common processes. Drivers that tie across different aspects of the Earth system and exert long-term control on the rock record include (1) tectonic processes associated with the structure, interactions, and configurations of the lithosphere, and (2) the secular evolution of

Figure 1. A: Temporal distribution of glaciations (Bradley, 2011), atmospheric (Atm) oxygen relative to present atmospheric level (PAL) (Berner et al., 2003; Canfield, 2005), and seawater sulfate (adapted from Farquhar et al., 2010; Pope and Grotzinger, 2003). B: Iron formation abundance (Bekker et al., 2010). C: Ages of ancient and modern passive margins (Bradley, 2008). D: Normalized seawater $\text{^{87}Sr}/\text{^{86}Sr}$ curve (Shields, 2007) and running mean of initial $\varepsilon_H$ in ~7000 detrital zircons from recent sediments (Cawood et al., 2013). E: Histogram of more than 100,000 detrital zircon analyses showing several peaks in their U-Pb crystallization ages over course of Earth history (Voice et al., 2011) that are very similar to ages of supercontinent assembly (timing of assembly shown). Also shown is apparent thermal gradient versus age of peak metamorphism for three main types of granulite facies metamorphic belts (Brown, 2007). UHT—ultrahigh temperature; HP—high pressure; UHP—ultrahigh pressure. F: Orogenic gold (adapted from Goldfarb et al., 2001). G: Volcanic-hosted massive sulfide (VHMS) deposits (Mosier et al., 2009). H: Anorthosite abundance (compiled from Ashwal, 2010; Frost and Frost, 2013; Parnell et al., 2012). I: Thermal ($T$, temperature) models for ambient mantle for Urey (Ur) ratios of 0.23 and 0.38 (Herzberg et al., 2010). J: Time series analysis of distribution of large igneous provinces (Prokoph et al., 2004). Period 1.7–0.75 Ga is highlighted.
Earth’s internal heat production. The absence of any change in the inferred frequency of large igneous provinces across the 1.7–0.75 Ga time period (Fig. 1), relative to preceding and succeeding intervals, suggests that processes within the deep mantle were not a significant factor.

Unusually, the configuration of core elements of the Nuna supercontinent over the period ca. 2.1–1.7 Ga continued until ca. 0.8 Ga, when the inferred succeeding supercontinent of Rodinia started to break up (Evans, 2013). Paleogeographic reconstructions suggest that the supercontinent assemblage straddled equatorial and temporal climatic zones throughout the intervening time frame; there is little or no evidence for continental fragments in polar latitudes (Evans, 2013, and references therein). A consequence of a limited breakup history is a paucity of passive margins in the range 1.8–0.8 Ga (Fig. 1; Bradley, 2008). This stable configuration in both space and time provides the primary constraint on the environmental stasis that characterizes the oceans, atmosphere, and biosphere (Brasier and Lindsay, 1998). In detail, the ocean was relatively warm and sulfidic euxinic (Farquhar et al., 2010), as evidenced by the absence of glacial deposits and iron formations. The subducted seawater Sr and zircon Hf isotopic signatures from 1.7 to 0.75 Ga likely reflect the long accretionary history and juvenile magmatism, combined with inferred ocean closure through dual subduction zones beneath the opposing Laurerian and Amazonian margins (Cawood et al., 2013; Spencer et al., 2013). The general trend of seawater Sr values is in part mimicked by seawater sulfate values along with decreasing oversaturation in seawater of calcium carbonate. Increasing input to seawater of sulfate around that time corresponds with Nuna assembly, suggesting that the source of the sulfate runoff was from chemical weathering of the continental crust in response to collisional orogenesis and growth of major mountain chains. The change in seawater proxies in the late Neoproterozoic corresponds to the closure through dual subduction zones beneath the opposing Laurentian and Amazonian margins (Cawood et al., 2013; Spencer et al., 2013). The general trend of seawater Sr values is in part mimicked by seawater sulfate values along with decreasing oversaturation in seawater of calcium carbonate. Increasing input to seawater of sulfate around that time corresponds with Nuna assembly, suggesting that the source of the sulfate runoff was from chemical weathering of the continental crust in response to collisional orogenesis and growth of major mountain chains. The change in seawater proxies in the late Neoproterozoic corresponds with the introduction of high-pressure metamorphic assemblages into the rock record and a pulse of crustal reworking associated with Gondwana

The termination of Earth’s middle age corresponds with Rodinia breakup at 0.75 Ga. Failing mantle temperatures enabled deeper levels of slab breakoff in collision zones, and the resultant greater depths to which continental crust was subducted prior to exhumation allowed the development of high-pressure metamorphic assemblages. Elements of the rock record that showed little change during Earth’s middle age show a strongly episodic distribution linked to the supercontinent cycles of Gondwana and Pangea (Fig. 1). The oxygen levels in both the atmosphere and deep oceans increased, and phosphate and evaporate deposits became widespread and provided a major spur for metazoans evolution. The impact of changing lithospheric behavior on surficial processes is likely an ongoing event in Earth history.
