ABSTRACT
The onset of the Dead Sea transform based on calcite age-strain analyses of mechanically twinned calcites. Direct dating of 30 syntectonic calcites from 10 different inactive fault strands of the transform indicates that the oceanic-to-continental plate boundary initiated between 20.8 and 18.5 Ma within an ~10-km-wide distributed deformation zone in southern Israel. Ages from the northern Dead Sea transform (17.1–12.7 Ma) suggest northward propagation and the establishment of a well-developed >500-km-long plate-bounding fault in 3 my. The dominant horizontal shortening direction recorded in the dated twinned calcites marks the onset of left-lateral motion along the evolving plate boundary. The observed changes in the strain field within individual fault strands cannot be simply explained by local “weakening effects” along strands of the Dead Sea transform or by gradual changes in the Euler pole through time.

INTRODUCTION
Direct dating of brittle fault activity and deciphering the associated stress-strain field are key factors in tectonic reconstructions and paleo-seismic studies. Yet, direct ages of fault activity coupled with robust strain directions along plate-bounding faults are rare. Here we focus on the Dead Sea transform (DST)—the plate boundary that accommodates the relative motion between the Africa (Sinai) and Arabia plates—and provide new insights into the onset and evolution of this seismically active system.

A host of stratigraphic and structural evidence paints a general picture of the evolution of the DST. There has been ~105 km of left-lateral offset across the boundary (Quennell, 1958; Freund et al., 1970; Garfunkel, 1981; Joffe and Garfunkel, 1987). The onset of this motion post-dates 22–20 Ma, based on offset magmatic dikes (Eyal et al., 1981), the ages of the oldest basin-fill sediments along the transform (Garfunkel, 1981), and additional kinematic considerations related to the opening of the Red Sea (Joffe and Garfunkel, 1987). This strike-slip motion may have been preceded by normal faulting, suggesting that the present DST was localized within an old faulted terrane (Bosworth et al., 2005; Avni et al., 2012). Mesosstructural analyses indicate regional NW–SSE horizontal shortening associated with the left-lateral motion along the transform (Eyal and Reches, 1983). The trajectories of this strain field vary locally adjacent to the transform, aligning either sub-parallel or sub-perpendicular to strands of the system (Garfunkel, 1981; Weinberger et al., 2009). This regional strain field was dominant from the Neogene to Recent. However, eastward migration of the Sinai-Arabia Euler pole through time has resulted in rearrangement of the plate boundary, causing local changes in the strain field (Gomez et al., 2007; Marco, 2007; Schattner and Weinberger, 2008; Weinberger et al., 2009).

Many aspects of the evolution of the DST are not yet understood. For example, when and where did the transform system initiate (Omar and Steckler, 1995; Wolfenden et al., 2004)? Did the transform propagate northward or southward (Ben-Avraham and Lyakhovsky, 1992; Omar and Steckler, 1995)? Was the strike-slip motion localized or distributed within a wider deformation zone (Wesnousky, 1988; Marco, 2007)? Did the system initiate by reactivation of pre-existing faults (Bosworth et al., 2005; Avni et al., 2012)? And, did the strain field fluctuate regionally through time (Eyal, 1996) or just locally adjacent to the transform (Garfunkel, 1981)? Understanding these issues of the archetypal DST may shed light on similar strike-slip boundaries elsewhere on Earth.

Here we reveal the early stages of the DST evolution by using two approaches: U-Pb calcite dating (Li et al., 2014; Coogan et al., 2016; Ring and Gerdes, 2016; Roberts and Walker, 2016) to obtain absolute time constraints on fault slip, and calcite twin analyses to decode the finite strain field related to long-term fault activity (Burkhard, 1993). The results provide for the first time combined U-Pb ages and paleo-strain directions of individual calcite crystals from fault zones.

METHODS AND RESULTS
We studied syntectonic calcite precipitates such as breccia cement, sheared fault coating, and associated microstructures were examined (Fig. 2; Fig. DR1 in the GSA Data Repository1) to assess the temporal relationships between deformation and calcite precipitation (Nuriel et al., 2012b). A total of 30 syntectonic calcite precipitates were dated by U-Pb laser ablation–multicollector–inductively coupled plasma–mass spectrometry (LA-ICPMS). The U-Pb calcite geochronology follows standard methods described elsewhere (Li et al., 2014; Coogan et al., 2016; Ring and Gerdes, 2016; Roberts and Walker, 2016) with several lab specifications (Kylander-Clark et al., 2013) and modifications (see Fig. DR2). For mass-bias correction of the measured 206Pb/238U and 207Pb/206Pb ratios, we used the 3.01 ± 0.012 (2σ) Ma calcite spoleothem ASH-15D standard.

Figure 1. Location maps and cross-section along the Dead Sea transform (DST), Israel. Triangles mark sampling sites of fault-related calcite precipitates. A: Setting of Guvta (H) and Newe Ative graben (NAV) fault zones in the northern, Hermon region. Inset shows general plate-tectonic configuration of left-lateral Dead Sea transform (DST). B: Setting of Gishron (GF), Yehoshafat (YF), Shelomo (SF), Roded (RD), Yotam (YG), Tsefahot (TS), and Elat (EF) fault zones in southern, Elat region; solid lines mark trace of major faults at surface, and dashed lines mark inferred location of major faults in subsurface (modified after Byeth et al., 2012, and Sneh and Weinberger, 2014). C: Schematic cross-section through Elat region showing ~10-km-wide deformation zone with several major approximately north-south-striking faults that form two prominent grabens (Shelomo and Yotam) and juxtapose mainly Proterozoic crystalline basement rocks against Cambrian to Neogene sedimentary sequence (Eyal, 1973) (modified after Marco, 2007).

DISCUSSION AND CONCLUSIONS

Combining the U-Pb ages with the shortening direction determined from calcite twins reveals a coherent picture for the onset and evolution of the DST. Left-lateral motion initiated by 20.8 ± 2.3 Ma in the southern, Elat part of the transform and reached the northern, Hermon region by 17.1 ± 0.3 Ma. These ages are compatible with northward propagation of fault activity to establish a well-developed, >500-km-long plate-bounding fault in 3 m.y., and provide further support to studies that show a northward progression of slip from the Gulf of Aqaba-Elat (Bar et al., 1974). These ages also support the chronological framework of the DST inferred by indirect methods (Eyal et al., 1981; Garfunkel, 1981) and exclude the possibility that the transform boundary initiated later at ca. 14 Ma (Bosworth et al., 2005). In the Elat shear zone, the oldest ages—20.8, 20.1, 19.0, 18.6, and 18.5 Ma—are from the westernmost and easternmost bounding faults (Gishron and Tsefahot fault previously dated by thermal ionization mass spectrometry (TIMS) (Mason et al., 2013; Vaks et al., 2013) and NIST-614 glass, respectively. Variation in the U-Pb ratios among individual spot analyses of single samples allows determination of a Tera-Wasserburg intercept age with 2σ errors better than 6% for most samples (see an example in Fig. 3 and in Fig. DR2). The ages of syntectonic calcite range from 21 to 6 Ma (n = 28; Fig. 4), and ages of 92 and 57 Ma (n = 2; Fig. DR2) were obtained for host-rock carbonate and an older generation of calcite veins, respectively.

Calcite twins mechanically at low differential stresses (~10 MPa) either during or shortly after calcite crystallizes in an active fault zone. While fault kinematics are susceptible to an instantaneous strain field during earthquake events (Fossen, 2010), calcite twin analyses can be used to infer the finite strain field. For calcite strain analyses, we used four-axis universal stage measurements of twin orientations and the crystallographic orientation of the host crystals to calculate the maximum shortening direction (ε1) using a least-squares technique (Groshong et al., 1984; see more in Fig. DR3). The maximum ε1 shortening direction is horizontal, ranging from approximately NNW-SSW to approximately north-south (7 samples) and to approximately NNE-SSW (9 samples) directions (Fig. 4; Fig. DR3). Only two fault samples have oblique ε1 shortening directions that are plunging 56°–51° (samples GF51 and YG3). Host-rock carbonate with an age of 92 Ma next to the Roded fault (sample RD3a) has a subvertical ε1 shortening direction that is plunging 68°. An older vein generation (sample NAV2Vb, 57 Ma) that is offset by DST-related structure (sample NAV3Vb) has east-west ε1 directions. Sample TS2 is very different both in age (6 Ma) and ε1 direction (east-west) and is therefore considered as an outlier.
zones; Fig. 1C), and these faults have maximum horizontal shortening directions that are compatible with left-lateral motion. Hence, the Elat region preserves a record of the oldest known part of the DST system so far. The results further reveal that the transform initiated within an ~10-km-wide distributional deformation zone (from the Gishron to the Tsefahot faults; Fig. 1C). The cessation of fault activity in the Elat shear zone at 12.7 Ma was followed by the formation of a flat erosion surface that truncates the structures (Fig. 1C).

The results do not support reactivation of preexisting normal faults, because calcite twins with subvertical maximum shortening directions are absent (see Fig. DR3). The dominant maximum horizontal shortening directions fluctuated between NNW-SSE and NNE-SSW during the period from 20.8 to 12.7 Ma. Such fluctuations in the strain field within individual segments cannot be simply explained by local “weakening effects” along fault strands of the DST (Garfunkel, 1981) or by gradual migration of the Euler pole through time (Gomez et al., 2007; Marco, 2007; Weinberger et al., 2009).
