Age-Related Impairment in Insulin Release
The Essential Role of β2-Adrenergic Receptor

Gaetano Santulli,1,2 Angela Lombardi,3,4 Daniela Sorrentino,1 Antonio Anastasio,1 Carmine Del Giudice,1 Pietro Formisano,4 Francesco Béguinot,4 Bruno Trimarco,1 Claudia Miele,4 and Guido Iaccarino5

In this study, we investigated the significance of β2-adrenergic receptor (β2AR) in age-related impaired insulin secretion and glucose homeostasis. We characterized the metabolic phenotype of β2AR-null C57Bl/6N mice (β2AR−/−) by performing in vivo and ex vivo experiments. In vitro assays in cultured INS-1E β-cells were carried out in order to clarify the mechanism by which β2AR deficiency affects glucose metabolism. Adult β2AR−/− mice featured glucose intolerance, and pancreatic islets isolated from these animals displayed impaired glucose-induced insulin release, accompanied by reduced expression of peroxisome proliferator-activated receptor (PPARγ), pancreatic duodenal homebox-1 (PDX-1), and GLUT2. Adenovirus-mediated gene transfer of human β2AR rescued these defects. Consistent effects were evoked in vitro both upon β2AR knockdown and pharmacologic treatment. Interestingly, with aging, wild-type (β2AR+/+) littersmates developed impaired insulin secretion and glucose tolerance. Moreover, islets from 20-month-old β2AR−/− mice exhibited reduced density of β2AR compared with those from younger animals, paralleled by decreased levels of PPARγ, PDX-1, and GLUT2. Overexpression of β2AR in aged mice rescued glucose intolerance and insulin release both in vivo and ex vivo, restoring PPARγ/PDX-1/GLUT2 levels. Our data indicate that reduced β2AR expression contributes to the age-related decline of glucose tolerance in mice. Diabetes 61:692–701, 2012

Impairment of glucose metabolism with age represents a major determinant of type 2 diabetes epidemics within the elderly population. The molecular mechanisms underlying these changes have not been fully elucidated and are likely attributable to multiple causes (1,2). Aging per se is associated with a continuous decrease in basal insulin release (3). The size of this effect is sufficient to increase the likelihood of developing abnormalities in glucose tolerance and even overt diabetes (2,4). The consequence of aging on glucose tolerance occurs in different species, having been identified in rats (5,6) as well as in humans (4,7,8). However, why insulin secretion deteriorates with aging remains a moot point.

The noradrenergic system provides fine-tuning to the endocrine pancreas activity through the function of α- and β-adrenergic receptors (ARs) (9,10). The reciprocal regulation exerted by insulin and the adrenergic system has been well documented through a large number of studies (11–13). More recent evidence shows that mice with simultaneous deletion of the three known genes encoding the βARs (β1, β2, and β3) present a phenotype characterized by impaired glucose tolerance (14). Studies with β2AR agonists further suggest that the β2AR may play an important role in regulating insulin secretion (15). In addition, different human polymorphisms in the β2AR gene have been associated with higher fasting insulin levels (16). Nevertheless, the impact of the β2AR subtype on glucose tolerance and insulin secretion is still unclear.

Similar to glucose tolerance, βAR function and responsiveness deteriorate with aging (17–20), but the precise mechanisms involved are unknown. However, current evidence indicates that aging may downregulate βAR signaling, β2AR in particular, by decreasing the expression of molecular components of the adrenergic signaling machinery (21–24). We have therefore hypothesized that age-dependent alterations in βAR function impair glucose-regulated insulin release by the pancreatic β-cells and may contribute to deterioration of glucose tolerance. To test this hypothesis, we explored the consequences of β2AR knockout on insulin secretion in mice and investigated the significance of the age-related changes in β2AR function with regard to glucose tolerance.

RESEARCH DESIGN AND METHODS

In vivo studies. We studied male mice with a homozygous deletion of the β2AR gene (β2AR−/−) and backcrossed >12 generations onto C57Bl/6N background. Founders were provided by Brian Kobilka (Stanford University, Stanford, CA) (25). Wild-type littersmates (β2AR+/+) were used as controls. The animals were housed in a temperature-controlled (22°C) room with a 12-h light/dark cycle in accordance with the Guide for the Care and Use of Laboratory Animals published by the National Institutes of Health (NIH publication no. 85-23, revised 1996), and experiments were approved by the ethics committee of the Federico II University. Mice were killed by cervical dislocation. Pancreata were excised and collected rapidly after mice were killed. Samples were weighted, fixed by immersion in 4% paraformaldehyde for histology, homogenized for determination of total insulin content, or snap-frozen in liquid nitrogen and stored at −80°C for subsequent analyses. For determination of insulin or glucagon content, pancreatic tissue was homogenized in acid ethanol and extracted at 4°C overnight. The acidic extracts were dried by vacuum, reconstituted, and subjected to insulin and glucagon measurements.

Glucose tolerance test and assessment of insulin secretion. Glucose tolerance test (GTT) was performed as previously described (9,26). Briefly, mice were fasted overnight and then injected with glucose (2 g/kg i.p.). Blood glucose was measured by tail bleeding (Glucose Analyzer II; Beckman Coulter, Brea, CA) at indicated time points. The assessment of insulin secretion before
and during glucose challenge was performed as previously described (9,27). Blood from the mandibular vein of overnight-fasted mice was collected at the indicated time for serum insulin assessment. The evaluation of glucagon secretion was performed by collecting blood from the mandibular vein of random-fed mice from the day of infection. Serum insulin and plasma glucagon were assayed by radioimmunoassay (Millipore, Billerica, MA).

**Histological analysis.** Immunohistochemistry was carried out on paraffin sections using the IHS rabbit insulin antibody or the N-17 goat glucagon antibody (1:200 dilution; both from Santa Cruz Biotechnology, Santa Cruz, CA). Goat anti-rabbit serum coupled with peroxidase (Immunotech, Marseille, France) was used as a secondary antibody. After primary antibody exposure, slides were incubated with biotinylated anti-rabbit or anti-goat IgG and peroxidase-labeled streptavidin (Dako Corporation). All reactions were revealed with diaminobenzidine. Sections were counterstained with hematoxylin and mounted (28,29).

**Ex vivo studies**

**Isolation of mouse pancreatic islets.** Islets of Langerhans were isolated and isolated islets were obtained by collagenase digestion (26,30). Briefly, mice were killed as described above, the fur was shaved with ethanol, and the abdomen was opened to locate and excise the pancreas. Digestion was completed with collagenase P (Roche Applied Sciences, Penzberg, Germany) in a shaking water bath (37°C) for 5–8 min. The digested pancreas was treated with DNase I (New England Biolabs, Ipswich, MA). The islets were hand-picked under a stereomicroscope using a 200-μm tuberculin syringe and Then 12 μL of islets were inoculated in layers using 3 μL of Adβ2AR or, as control, an empty expression cassette derived from pcDNA3.2/PPAR-γ2AR (33) and the validated use of the adenoviruses expressing the β2AR in vivo and ex vivo. Adenovirus-mediated reinstallation of β2AR in vivo and ex vivo. Twenty-month-old β2AR+/− mice were anesthetized by isoflurane (4%) inhalation and maintained by mask ventilation (isoflurane 1.8%) (28). After laparotomy, we identified and mobilized the distal pancreas and we performed two injections (50 μL each) of adenovirus (7 × 10^10 plaque-forming units [pfu]/mouse) using a 30-gauge needle. Given the high homology between the human and mouse β2AR (35) and the validated use of the adenoviruses expressing the human β2AR (Adβ2AR) for in vivo gene transfer (34–36), we used the human Adβ2AR or, as control, an empty expression cassette derived from pcDNA3.2/PPAR-γ2AR (AdEmpty), kindly provided by Walter J. Koch, Jefferson University (Philadelphia, PA). Finally, abdominal incision was quickly closed with 0 silk suture, and animals were observed and monitored until recovery. Isolated islets were injected (12 × 10^4 pfu/islet) with Adβ2AR or AdEmpty. After 3 h incubation with the adenoviruses, pancreatic islets were incubated with fresh medium and under normoxic conditions (95% air, 5% CO₂) at 37°C for 24 h.

**In vitro studies.** The INS-1E β-cells (provided by P. Maechler, University of Pittsburgh, PA), or 1 μmol/L isoproterenol (Tocris Bioscience, Ellisville, MO). The reaction was stopped by addition of 50 mmol/L HCl and neutralized with the Nac cells. The cAMP levels were normalized to the protein concentration.

**Statistical analysis.** All data are presented as means ± SE. Statistical differences were determined by one-way or two-way ANOVA as appropriate, and Bonferroni post hoc testing was performed when applicable. A P value <0.05 was considered significant. Statistical analysis was performed using GraphPad Prism (version 5.01; GraphPad Software Inc., San Diego, CA).

**RESULTS**

**Metabolic phenotype of β2AR−/− mouse.** To investigate in vivo the relevance of the β2AR gene in the regulation of insulin secretion, we compared the metabolic phenotype of adult (6 months old) β2AR−/− and β2AR+/− mice. Blood glucose was significantly higher in the null mice compared with that in their wild-type littermates both upon fasting and under random feeding conditions (Table 1). In addition, their fasting serum insulin levels were significantly reduced (Table 1). Upon glucose loading (GTG), the β2AR−/− mice displayed a marked reduction in glucose tolerance (Fig. A and B). In β2AR−/− mice, we observed a threefold increase in insulin secretion 3 min after intraperitoneal glucose injection, presumably corresponding with the peak of first-phase insulin release. This was followed by a decrease at 10

FIG. 1. Metabolic profile of β2AR−/− mice. Six-month-old β2AR−/− mice and their wild-type littermates (β2AR+/+) were fasted for 16 h and subjected to intraperitoneal glucose loading (2 g/kg body weight). Blood glucose (A and B) and serum insulin (C and D) were monitored for 120 min after glucose administration (n = 14–18 animals per group). β2AR−/− mice displayed glucose intolerance (A) and impaired insulin secretion (C). We calculated the AUC from glucose (B) and insulin excursion (D) curves. Peak insulin–to–peak glucose ratio (E) represents β-cell function, as better described in RESEARCH DESIGN AND METHODS. Bars represent means ± SE. *P < 0.05 vs. β2AR+/+, Bonferroni post hoc test. AUC, area under the curve.
min and then a gradual increase over 30 min that may indicate a second-phase response (27,41).

In β2AR−/− mice, the early phase of insulin secretory response to glucose was reduced by more than twofold. The late response was also significantly impaired in the β2AR−/− compared with β2AR+/+ mice (Fig. 1C and D). The peak insulin-to-peak glucose ratio was also decreased (Fig. 1E), further indicating impaired insulin response to hyperglycemia in the null mice.

To investigate whether the alterations in glucose tolerance identified in the β2AR−/− mice were contributed by deranged glucagon release, we further measured blood glucose and plasma glucagon levels 30 min after insulin administration. Indeed, insulin administration determines a fall in blood glucose and a counterregulatory rise in plasma glucagon (2,30). However, β2AR−/− and β2AR+/+ mice exhibited comparable glucose and glucagon responses to insulin administration (Supplementary Fig. 1A and B). Pancreatic islet histology also did not show any significant difference in these mice (Fig. 2A), similar to total insulin and glucagon pancreatic content (Fig. 2B and C).

We then posed the further question of whether the reduced glucose insulin secretion observed in the β2AR−/− mice in vivo may represent the direct consequence of the β2AR−/− lack in the β-cells or whether it is indirectly mediated by other regulatory factors. To answer this question, we analyzed glucagon effect on islets isolated from the null mice. As shown in Fig. 2D, these islets responded poorly to increased glucose concentration in the culture medium compared with the islets from their wild-type littermates but were fully responsive to KCl depolarization.

**Islets and β-cell profiling after β2AR deletion.** To gain further insight into the mechanism leading to impaired insulin secretion in mice lacking β2AR, we profiled the expression of different genes relevant to β-cell regulation by real-time RT-PCR of islet mRNA. As shown in Fig. 3A and B, mRNA levels of both PDX-1 and GLUT2, two major genes involved in β-cell function, were decreased in islets from β2AR−/− mice by 75 and 60%, respectively. Also, mRNA levels of the PDX-1/GLUT2 upstream regulator PPARγ were decreased by 54% compared with islets from wild-type mice (Fig. 3C). Reliable results were obtained in
immunoblotting experiments (Fig. 3D and E). PDX-1 and GLUT2 mRNAs were also reduced to a similar extent in total pancreatic tissue from the $\beta_2$AR$^{-/-}$ mice (data not shown).

We then sought to demonstrate whether these abnormalities in gene expression were directly caused by $\beta_2$AR silencing. To pursue this objective, we silenced with a specific shRNA (Supplementary Fig. 2) the $\beta_2$AR gene in the glucose-responsive INS-1E $\beta$-cell line (INS-1E$\beta_{sh2AR}$) (Fig. 4A and B). As shown in Fig. 4C, this specific knockdown impaired glucose-induced insulin secretion by 58% in these cells. A similarly sized effect was achieved by treatment with the specific $\beta_2$AR antagonist ICI, while the $\beta_2$AR agonist fenoterol showed an opposite action (Supplementary Fig. 3). Consistent with our ex vivo results, the INS-1E$\beta_{sh2AR}$ displayed a reduction in PDX-1, GLUT2, and PPAR$\gamma$ mRNA (Fig. 4D–F) and protein levels (Fig. 4G and H). Interestingly, transient transfection of a PPAR$\gamma$ cDNA in INS-1E$\beta_{sh2AR}$ $\beta$-cells increased glucose-induced insulin secretion compared with the wild-type INS-1E control $\beta$-cells (Fig. 4C). In addition, overexpression of PPAR$\gamma$ prevented the downregulation of both PDX-1 and GLUT2 occurring in the INS-1E$\beta_{sh2AR}$ $\beta$-cells (Fig. 4D–H). Consistently, treatment of INS-1E $\beta$-cells with ICI decreased PDX-1 and GLUT2 mRNA and protein levels, while PPAR$\gamma$ overexpression completely prevented the effect of ICI (Supplementary Fig. 3B–D), suggesting that $\beta_2$AR controls insulin secretion through a PPAR$\gamma$/PDX-1–mediated mechanism.

To better define the $\beta_2$AR downstream mechanism leading to PPAR$\gamma$ activation, we assessed the cAMP levels in these cells, observing an impaired production of cAMP in INS-1E$\beta_{sh2AR}$ $\beta$-cells both in basal condition and after stimulation with the $\beta_2$AR agonist isoproterenol (Supplementary Fig. 4A). Accordingly, to rule out possible involvement of other components of $\beta_2$AR signaling machinery, we assessed the protein level of AC-VI, GRK2, and G$\alpha_6$, and we found no significant difference (Supplementary Fig. 4B and C). Parallel results were obtained in ex vivo experiments, performed to investigate the possible age-related alterations in the $\beta_2$AR transduction pathway, comparing pancreatic islets isolated from adult (6 months old) and old (20 months old) $\beta_2$AR$^{-/-}$ mice (Supplementary Fig. 4D and E).

**$\beta_2$AR overexpression rescued the age-related impairment in insulin release.** Based on radioligand binding and real-time RT-PCR analysis, the expression of both $\beta_2$AR protein and mRNA was significantly decreased in islets from aged (20 months old) $\beta_2$AR$^{-/-}$ mice compared with those isolated from adult (6 months old) mice (Fig. 5A and B). PDX-1, GLUT2, and PPAR$\gamma$ expression (both in terms of mRNA and protein level) was also reduced, and insulin release in response to glucose, though not that evoked by KCl depolarization, was impaired in islets from the aged mice (Fig. 5C–H), suggesting that the reduced $\beta_2$AR density constrains islet glucose response in these animals. To prove this hypothesis, we used an adenoviral construct driving overexpression of human $\beta_2$AR in mouse islets. Interestingly, infection of islets isolated from wild-type old mice with this construct induced a twofold increase in $\beta_2$AR expression (Fig. 5A and B) and returned glucose-induced insulin secretion to levels comparable with those of islets from 6-month-old mice (Fig. 5C) accompanied by restored expression of PDX-1, GLUT2, and PPAR$\gamma$ (Fig. 5D–H).

In the in vivo setup, 20-month-old $\beta_2$AR$^{-/-}$ mice exhibited a significant reduction in fasting serum insulin levels (Table 2) accompanied by impaired glucose tolerance and...
insulin response upon GTT (Fig. 6A–E). We have therefore designed a gene therapy protocol aimed to prove that these abnormalities can be corrected by restoring β2AR density. Accordingly, we infected the pancreas of aged mice by Adβ2AR injection. This injection effectively rescued β2AR expression in the pancreatic tissue, returning it to levels comparable with those of 6-month-old mice (Supplementary Fig. 5A and B), and restored the expression of PDX-1, GLUT2, and PPARγ (Supplementary Fig. 5C–E). Injections in the distal pancreas did not induce β2AR expression in other tissues, such as the liver (Supplementary Fig. 6A and B) or the skeletal muscle (Supplementary Fig. 6C and D).

These effects were paralleled by significant improvement in glucose tolerance and insulin secretion during GTT (Fig. 6A–E). Fasting insulin levels also increased, reaching values similar to those measured in 6-month-old mice (Table 2), further underlining the relevance of β2AR function in enabling adequate pancreatic β-cell response to hyperglycemia.

**DISCUSSION**

In the present work, we provide evidence that β2AR gene deletion in mice causes reduction of glucose-stimulated insulin release by pancreatic β-cells. This phenotype is reminiscent of that observed in mice with targeted β-cell disruption of the Gas gene (30). In these mice, however, the impairment of Gas prevented response to multiple Gas-related receptors, causing a severe phenotype, with gross abnormalities in pancreatic islets. Interestingly, in islets from β2AR−/− mice, PPARγ expression was reduced by 50%, leading to repression of the PPARγ downstream molecules PDX-1 and GLUT2, two key effectors of β-cell function (26,42,43). This downregulation resulted in a clear impairment in insulin release, though islet architecture and insulin content were not affected by the β2AR gene deletion.

Rosen et al. (44) showed that islets from mice with targeted elimination of PPARγ in β-cells were approximately twice as large as those from control mice. Thus, we can speculate that in our model the 50% reduction in
PPARγ levels is sufficient to restrain β-cell function without altering islet mass. The mechanistic significance of β2AR gene knockout was further sustained by in vitro studies in the INS-1E pancreatic β-cells, showing that the silencing of the β2AR as well as the pharmacological treatment with a specific β2AR antagonist impaired glucose response and down-regulated PPARγ expression, reducing both PDX-1 and GLUT2 levels. No alteration of αARs was observed instead (data not shown). In addition, treatment with the β2AR agonist fenoterol activated PPARγ/PDX-1/GLUT2 signaling, indicating that, at least in part, β2AR controls insulin secretion through this pathway. Indeed, in this study we show that exogenous PPARγ expression in INS-1E β-cells silenced for β2AR led to recovery of PDX-1/GLUT2 levels and glucose-stimulated insulin secretion. This finding is supported by recent evidence that directly relates β2AR to PPARγ (42,45–47), a key element in the process of insulin secretion.

FIG. 6. Adenoviral vector-mediated β2AR gene transfer in the mouse pancreas rescued age-related reduction in glucose tolerance. Blood glucose levels (A) and serum insulin (C) after 120 min of glucose administration (n = 14–18 animals per group). We calculated the AUC from glucose (B) and insulin excursion (D) curves. Twenty-month-old β2AR** mice showed glucose intolerance (A and B), impaired insulin secretion (C and D), and also an impairment in β-cell function, evaluated measuring the peak insulin-to-peak glucose ratio (E). All of these parameters were restored after Adβ2AR in vivo infection. *P < 0.05 vs. β2AR** at 6 months (mos) of age, Bonferroni post hoc test. (See also Supplementary Figs. 5 and 6.)
secretion that has also recently been investigated in aging (43–48). Our results are consistent with these observations, sustaining also the hypothesis that cAMP levels could act as a connecting link through which β2AR signaling leads to activation of PPARγ (49,50). Moreover, the cAMP assays, performed both in INS-1E<sub>sh</sub>β2AR pancreatic β-cells and in islets isolated from aged mice, showed an impairment in basal conditions and after stimulation with isoproterenol, while the responses to NaF and forskolin were not affected. Also, Go<sub>a</sub> and AC-VI protein levels were not significantly different among the explored settings. This combination of events is usually observed in models of β2AR gene deletion or impaired β2AR signaling (18,34).

Whether and to what extent β2AR gene knockout in liver and peripheral tissues affects glucose homeostasis in the β2AR<sup>−/−</sup> mice remain to be conclusively addressed. Indeed, variations at the β2AR locus have also been reported to associate with insulin resistance in type 2 diabetic patients (16). However, as shown in this work, the impaired glucose tolerance of β2AR<sup>−/−</sup> mice is likely contributed by the defective β-cell function, as indicated by the major effect of β2AR lack on glucose-evoked insulin secretion.

In humans, glucose tolerance declines with age, resulting in a high prevalence of type 2 diabetes and impaired glucose tolerance in the elderly population (2,8). How, at the individual level, glucose tolerance declines remains unclear, but it is likely determined by multiple factors including diminished insulin secretion (3,7). In rat models and in humans, a progressive decline in β-cell activity with age has been documented (4,6). In the present work, we show that the same occurs in the 5TBI/6N mouse and is paralleled by the development of abnormal glucose tolerance. Similar to previous findings in several human tissues (18–21,24), our results show that these changes are accompanied by reduced β2AR levels in mouse pancreatic islets. The decreased β2AR density in islets from aged mice recapitulates the mechanisms leading to the insulin secretory defect occurring in β2AR-null mice, indicating that it may contribute to the age-related impairment in glucose tolerance. Indeed, both in vivo and ex vivo experiments of β2AR gene transfer revealed that recovery of normal β2AR levels rescued insulin release and glucose tolerance in aged mice. Thus, in the mouse model, progressive decline of islet β2AR density appears to contribute to the reduction in glucose tolerance that accompanies aging. Whether the same also occurs in humans needs to be clarified and is currently under investigation in our laboratory.

In conclusion, we have shown that β2AR physiologically regulates pancreatic β-cell insulin secretion by modulating PPARγ/PDX-1/GLUT2 function. Reduced β2AR expression contributes to the age-dependent deterioration of glucose tolerance.
