Abstract

Purpose: To determine the immunologic effects of neoadjuvant chemotherapy plus ipilimumab in early-stage non-small cell lung cancer (NSCLC) patients.

Experimental Design: This is a single-arm chemotherapy plus phaselipilimumab phase II study of 24 treatment-naive patients with stage IB–IIB NSCLC. Patients received neoadjuvant therapy consisting of 3 cycles of paclitaxel with either cisplatin or carboplatin and ipilimumab included in the last 2 cycles.

Results: Chemotherapy alone had little effect on immune parameters in PBMCs. Profound CD8+ dependent activation of both CD4 and CD8 cells was observed following ipilimumab. Significant increases in the frequencies of CD4+ cells expressing activation markers ICOS, HLA-DR, CTLA-4, and PD-1 were apparent. Likewise, increased frequencies of CD8+ cells expressing the same activation markers, with the exception of PD-1, were observed. We also examined 7 resected tumors and found higher frequencies of activated tumor-infiltrating lymphocytes than those observed in PBMCs. Surprisingly, we found 4 cases of preexisting tumor-associated antigens (TAA) responses against survivin, PRAME, or MAGE-A3 present in PBMC at baseline, but neither increased frequencies nor the appearance of newly detectable responses following ipilimumab therapy. Ipilimumab had little effect on the frequencies of circulating regulatory T cells and MDSCs.

Conclusions: This study did not meet the primary endpoint of detecting an increase in blood-based TAA T-cell responses after ipilimumab. Collectively, these results highlight the immune activating properties of ipilimumab in early-stage NSCLC. The immune profiling data for ipilimumab alone can contribute to the interpretation of immunologic data from combined immune checkpoint blockade immunotherapies. Introduction

Lung cancer is the leading cause of cancer-related deaths in the United States (1). Early-stage non–small cell lung cancer (NSCLC) is potentially curable, and there appears to be a benefit to neoadjuvant platinum-based chemotherapy in patients with locally advanced NSCLC (2). The consensus of data suggests that preoperative chemotherapy in stage II and IIIA NSCLC provides a survival benefit compared with surgery alone (3–5). A significant number of patients who receive neoadjuvant chemotherapy followed by surgery for stage II/III NSCLC experience relapse of their lung cancer and, therefore, novel therapeutic approaches are needed.

Ipilimumab is a human mAb that binds CTLA-4 on effector T cells. CTLA-4 is upregulated following T-cell activation as a regulatory mechanism to prevent overactivation and immunopathogenesis. The binding of ipilimumab to CTLA-4 enhances the costimulation of T cells by allowing CD28 binding to members of the B7 family on the antigen-presenting cell. Ipilimumab (Yervoy) is an effective, FDA-approved therapy in metastatic melanoma (7, 8).

Immune therapy has transformed the treatment of advanced-stage NSCLC, with PD-1 checkpoint inhibitors producing durable responses lasting for years (9–12). Clinical trials combining CTLA-4 and PD-1 checkpoint inhibitors have shown that the addition of ipilimumab to nivolumab exhibited promising activity in a large cohort of patients with untreated advanced stage NSCLC (13). The combination of ipilimumab and nivolumab alone and with chemotherapy is being studied in large clinical trials with advanced-stage NSCLC and as well as preoperative therapy in early-stage NSCLC (13). Understanding the biologic...
Ipilimumab Induced T-Cell Activation in NSCLC

**Translational Relevance**

This study is one of the first immune profiling efforts to characterize the immune response to ipilimumab in early-stage non-small cell lung cancer (NSCLC). Our findings provide immunologic evidence supporting the use of ipilimumab to induce T-cell activation in NSCLC. Notably, we demonstrate that CD8 T-cell activation seen after ipilimumab therapy is CD28 dependent and the expression of CD28 may improve the efficacy of ipilimumab. Furthermore, ipilimumab did not affect the frequency of regulatory T cells or myeloid-derived suppressor cells (MDSC), or PD-1 expression on CD8 T cells. With the rising use of immunotherapies in the treatment of NSCLC, the optimal immunotherapy or combination of immunotherapies will require the promotion of T-cell activation, migration into the tumor microenvironment, and avoidance of T-cell inhibition, and long-lasting cytotoxic function. Collectively, ipilimumab serves an important function in strengthening the antitumor response.

**Materials and Methods**

**Patients and treatment**

Eligible patients were 18 years of age or older with histologically proven clinical stage IB, II, IIA, or IIB lung cancer. Eligibility criteria included histologic diagnosis of NSCLC, adequate organ function, no autoimmune disease, PET/CT scan, and plasma were separated by Ficoll density gradient centrifugation, and PBMCs were resuspended in a 90% FBS (Gemini) and 10% DMSO (Sigma-Aldrich) solution. PBMCs were viable cryopreserved and stored in vapor phase liquid nitrogen, whereas plasma was frozen and stored at −80°C for future use. Tumor and tumor-infiltrating lymphocytes (TIL) were isolated from freshly resected tumor tissue using the Miltenyi Tumor Dissociation Kit and GentleMACS mechanical dissociator in accordance with the manufacturer’s recommendations for lung tumor. Following disaggregation, the tumor cells and TILs were viably cryopreserved in a manner identical to PBMCs described above.

**Flow cytometry analysis**

Immune profiling of PBMCs and TILs was performed using two polychromatic flow cytometry panels: an immune cell subsetting panel (Supplementary Table S1A) and a T-cell function panel (Supplementary Table S1B). Because of the complexity of the subsetting panel, CD8+ frequencies were ascertained as CD4- negative cells within the CD3+ gate. For staining with the immune cell subsetting panel, two million PBMCs or TILs were first incubated in a 12 x 75 mm staining tube, with Fc Block (BD Biosciences), followed by a surface stain with ICOS, CD14, CD16, CD19, CD20, CD56, PD-1, CD28, HLA-DR, Viability dye, CD3, CD25, CD4, CD33, and CD11b for 25 minutes at 4°C. Following cell surface staining, cells were treated with the FOXP3 Fix/Perm solution (Bioscience) for 45 minutes at 4°C. Intracellular staining was then performed for 30 minutes at 4°C using fluorescent antibodies against FOXP3 and CITA-4. Matched isotype controls were used for ICOS, CD14, HLA-DR, CITA-4, and FOXP3. Cells were fixed with 1% paraformaldehyde (Sigma-Aldrich) and acquired on a BD LSRII flow cytometer.

For staining with the T-cell function panel, two million PBMCs or TILs were plated in a 96-well plate in RPMI + 10% FBS. Cells were left untreated or stimulated with overlapping peptide pools (15-mers with 11 aa overlaps) representing MAGE-A3, PRAME,
and survivin (IPT), along with anti-CD3 and anti-CD28 as a positive control and cells in media alone as a negative control. All conditions also included anti-CD107a for the duration of the stimulation and cells were incubated for 18 hours at 37°C in 5% CO₂ humidified incubator. At 18 hours, Brefeldin A and Monensin (BD Biosciences) were added to all tubes and incubated for an additional 6 hours. After the stimulation period, cells were surface stained with 50 μL of a cocktail mix consisting of fluorescent conjugates for CD45RA, CCR7, CD14, and viability dye for 25 minutes at 4°C. Following cell surface staining, cells were treated with cytotoxic/cytoperm (BD Biosciences) in accordance with the manufacturer’s recommendations. Intracellular staining was then performed for 25 minutes at 4°C using fluorescent antibodies against TNFα, IFNγ, IL2, CD4, CD3, CD8, CD154, and CD69. Isotype controls were used for TNFα, IFNγ, CD45RA, CD107a, CCR7, and IL2. Cells were fixed with 1% paraformaldehyde and acquired on a LSRII flow cytometer (BD Biosciences).

Statistical analysis

Student t tests were used to assess differences in cell frequencies between visits. OS was defined as the time between the initiation of protocol therapy and date of death or last follow-up. Kaplan-Meier methods were used to describe overall survival. Analyses were not adjusted for multiple testing. Flow cytometric analysis was performed using Flowjo software (Tree Star). Statistical analysis was performed using Prism software (GraphPad) and SAS (version 9.4).

Results

Patients and treatment

Twenty-four eligible patients with NSCLC were enrolled between March 2013 and December 2015 and received neoadjuvant therapy on TOP1201: 12 (50%) female, 23 (96%) current or former smokers, 15 (62%) adenocarcinoma, 9 (37%) squamous carcinoma, and median age of 65 years (Supplementary Table S2). Three patients (13%) were lung cancer stage 2A, 2 (8%) were stage 2B, and 19 (79%) were stage 3A with 18 (75%) patients having pretreatment pathologically positive N2 lymph node metastases. Surgical resection post-ipilimumab included 14 (58%) patients with a partial response (PR), 8 (33%) with stable disease (SD), and 2 (8%) with progression (PD). Median OS was 29.2 months [95% confidence interval (CI), 22.1–∞], whereas 12-month OS was 82.2% (95% CI, 59.2–92.9) and 24-month OS was 73.0% (95% CI, 44.1–88.6) for all patients initiating neoadjuvant therapy. There have been no deaths at 24 months for the patients who underwent surgical resection of their lung cancer.

Uregulation of activation markers on CD4 and CD8 T cells after ipilimumab therapy

Flow cytometry analyses were performed on PBMCs collected at baseline (V1), after chemotherapy alone (V2), and after chemotherapy plus ipilimumab (V3) to profile the effect of ipilimumab on the immune parameters of patients with NSCLC (Fig. 1A). The immune subsetting panel consisted of 17 unique immune markers that identify both innate and adaptive cell types along with specific subsets (Supplementary Table S1). Markers, including ICOS, HLA-DR, CTLA-4, and PD-1 are associated with T-cell activation. Similar expression patterns in samples from V1 and V2 suggest that chemotherapy alone had little effect on lymphocyte activation. In contrast, ipilimumab had a broad activating effect on both CD4 and CD8 lymphocyte populations, as evidenced by the increased marker expression at V3 compared with baseline. The mean frequencies and corresponding SDs of positive subsets of CD4 T cells at V1 versus V3 for ICOS were 8.89; 3.25 versus 23.59; 7.51, for HLA-DR-positive were 7.06; 3.89 versus 14.80; 5.56, for CTLA-4-positive were 17.20; 6.48 versus 29.39; 10.52, and for PD-1-positive were 3.51; 3.12 versus 6.30; 4.34 (Fig. 1). For CD8 T cells, the frequency and corresponding SDs of ICOS-positive (4.91; 1.72 vs. 11.36; 5.30), HLA-DR-positive (14.35; 8.61 vs. 35.85; 12.60), and CTLA-4-positive (14.35; 8.61 vs. 35.85; 12.60) cells significantly increased after ipilimumab therapy, but PD-1 frequency and corresponding SD on CD8 T cells remained unchanged from V1 to V3 (5.51; 5.50 vs. 5.50; 5.32). Stratification of lymphocyte activation by overall response after neoadjuvant cycle 3 did not reveal differences over time between the PD, SD, and PR patients (Supplementary Fig. S1). An extended comparison of immune subsets and activation phenotypes of CD4 and CD8 T cells is listed in Supplementary Table S3. Overall, ipilimumab had a profound effect on CD4 and CD8 T-cell activation regardless of the clinical response.

TILs in NSCLC are highly activated

On the basis of the impact of ipilimumab on the expression pattern of activation markers on PBMCs, we performed a parallel analysis of ICOS, CTLA-4, HLA-DR, and PD-1 expression on TILs isolated from tumors of 7 patients who underwent resection and for which there was adequate excess tumor to perform
disaggregation of TILs, approximately 1 gram. Relative to the expression of these markers on peripheral T cells at visit 3, tumor-derived CD4 T cells expressed higher frequencies of ICOS (TIL mean with SD vs. PBMC mean with SD; 60.44; 6.84 vs. 23.59; 7.51), CTLA-4 (60.30; 25.81 vs. 29.39; 10.52), HLA-DR (82.31; 22.14 vs. 14.80; 5.56), and PD-1 (36.61; 11.33 vs. 6.30; 4.34; Fig. 2A). The frequencies of activated CD8 T cells were also higher in TILs based on the expression of ICOS (TIL vs. PBMC; 32.84; 9.45 vs. 11.36; 5.30), CTLA-4 (43.43; 19.87 vs. 35.85; 12.60), HLA-DR (87.10; 15.70 vs. 35.85; 12.60), and PD-1 (35.50; 16.94 vs. 5.50; 5.32; Fig. 2B). Although we did not have access to pretreatment tumor samples for comparison, the highly activated phenotype of the CD4 and CD8 TILs is indicative of an immunogenic tumor microenvironment.

Magnitude of T-cell activation is dependent on CD28 expression

A recent report by Kamphorst and colleagues (16) highlighted the finding that proliferating CD8 T cells in the peripheral circulation of lung cancer patients following PD-1 therapy predominantly expressed CD28. Although a proliferation marker was not included among our profiling panels, we sought to determine whether the post-ipilimumab activated CD8 T cells also coexpressed CD28. CD28 expression did not change in response to chemotherapy or ipilimumab (Fig. 3A). However, dissection of the CD8 T cells based on CD28 expression revealed that the ipilimumab-induced activation of CD8 T cells was CD28 dependent. The mean frequencies and corresponding SDs of ICOS (9.41; 3.47 vs. 24.71; 7.85) or CTLA-4 (4.28; 1.91 vs. 9.12; 4.34 vs. 24.71; 7.85) were significantly higher in the CD28-dependent T cells (Fig. 3B).
3.41) in CD28<sup>+</sup> T cells were significantly higher at V3 than V1 or V2 (Fig. 3B and C). The singular exception was the frequency of V3 CD8<sup>+</sup> T cells expressing HLA-DR, where the frequencies and corresponding SDs among CD28<sup>-</sup> and CD28<sup>+</sup> populations were similar (Fig. 3D). Overall, our results provide support that ipilimumab-induced activation of CD8 T cells is CD28 dependent.

Tumor-associated antigen-specific T-cell reactivities
After observing a significant increase in the expression of activation markers after ipilimumab therapy, we next examined whether this increase was associated with increases in functional TAA-specific CD4 or CD8 T-cell responses. Functional T-cell responses, reflected by intracellular accumulation of IFNγ, TNFα, and IL2 as well as surface expression of the degranulation marker

Figure 3.
Increase in CD8 T-cell activation following ipilimumab treatment is CD28 dependent. A, Composite data from 24 patients showing the fraction of CD8 T cells expressing CD28 at pretreatment (V1), postchemotherapy only (V2), and postchemotherapy and ipilimumab (V3) timepoints. B–D, Comparison of ICOS, CTLA-4, and HLA-DR expression on CD28<sup>-</sup> and CD28<sup>+</sup> CD8 T cells. Statistical significance is represented by *, P < 0.05 and ****, P < 0.0001. Mean and SD are shown.
CD107a, were examined following PBMC stimulation with overlapping peptide pools representing 3 of the most prevalent antigens found in NSCLC (17–19), namely MAGE-A3, survivin, and PRAME. Among 24 NSCLC patients in this study, CD4 or CD8 T-cell responses to MAGE-A3, survivin, or PRAME were detectable in 4 patients (Fig. 4). The responses of each patient varied in the antigen-specificity that induced the highest frequency of IFNγ positivity and T-cell subset that was responsive to antigen stimulation. Among the patients with IFNγ+ responses, the majority of T-cell responses were polyfunctional, as we also observed intracellular production of TNF-α, and expression of CD107a (data not shown). Collectively, in patients with detectable T-cell responses to MAGE-A3, survivin, or PRAME, these responses were present at baseline before treatment, and ipilimumab therapy had little or no effect on their relative frequencies, although several appeared to decline following ipilimumab treatment. No new anti-TAA reactivities were observed in conjunction with ipilimumab therapy, nor were any TAA reactivities detected within the tumor microenvironment of the seven resected tumors available for study (data not shown). Unfortunately, none of the 4 patients who had preexisting TAA reactivities at baseline had tumor resections and, therefore, we did not have an opportunity to profile the functional status of their TILs.

**Effect of ipilimumab on regulatory T cells and myeloid-derived suppressor cells**

To determine whether the ipilimumab induced T-cell activation was accompanied by a compensatory decrease in putative-suppressive cell populations, we examined the changes in frequencies of regulatory T cells (Treg) and myeloid-derived suppressor cells (MDSC) from baseline (V1) to post-neoadjuvant chemotherapy plus ipilimumab (V3). From chemotherapy only to post-ipilimumab therapy, the median frequency of CD4+CD25+FOXP3+ Tregs increased slightly by 1.05% (P = 0.012; Fig. 5A). Further examination of CTLA-4+ Tregs revealed no changes in this subset after ipilimumab treatment. No new anti-TAA reactivities were observed in conjunction with ipilimumab therapy in patients with advanced malignant melanomas suggested that the presence of high levels of MDSC (i.e., >15%) in the peripheral blood at baseline predicted nonresponsiveness to ipilimumab therapy (20). Collectively, the frequency of MDSCs,
identified as CD14<sup>+</sup> cells gated off the lineage negative, HLA-DRlow/negative population, remained unchanged after ipilimumab therapy (Fig. 5B). Outlying MDSC frequencies (>15%) by 3 patients were not predictive of clinical outcomes, as 2 of the 3 patients had a PR response and the third patient had a response of SD. Overall, ipilimumab had little to no effect on the frequency of circulating Tregs and MDSCs.

**Discussion**

Immune checkpoint therapy has transformed the care of advanced-stage NSCLC (9–12). Combination immune therapy, including CTLA-4 checkpoint blockade, has shown promise compared with PD-1 checkpoint blockade alone (13). Understanding how immune therapy combinations work by themselves and together to overcome immune resistance mechanisms will require an understanding of the activation and inhibitory factors associated with each individual immune therapy component. Randomized phase III trials studying chemotherapy with or without ipilimumab in advanced squamous NSCLC showed no survival benefit for the addition of ipilimumab to chemotherapy (NCT01285609, data available in clinicaltrials.gov). However, the combination of ipilimumab and the anti-PD1 antibody nivolumab in untreated advanced NSCLC showed a response rate of approximately 40% (13). Ipilimumab is being studied in randomized trials in combination with PD1 checkpoint immune therapy for untreated early and advanced stage NSCLC (NCT02998528, NCT02477826). Therefore, while single-agent CTLA-4 blockade is no longer being studied in NSCLC, ipilimumab is being actively studied in combination immune therapy in multiple large randomized trials in lung cancer, and the immune profiling data reported here is of particular interest in helping to understand how CTLA-4 inhibitors may be best used in immune therapy combinations. To our knowledge, this is the first report of a broad immunologic study in early-stage NSCLC for the activation of blood T cells, MDSCs, and Tregs at baseline, after chemotherapy, and after ipilimumab. We also report some of the first data supporting ipilimumab immune activation in TILs from early-stage NSCLC.

The patients referred by the surgical service for this trial had either a large primary tumor and/or mediastinal lymph node metastasis that needed to respond to neoadjuvant therapy to make the cancer appropriate for surgical resection by our institutional standard of care. Thus, only 13 of 24 patients underwent resection mostly because of tumor stage after neoadjuvant therapy, rather than some side effect from neoadjuvant treatment. The adverse events on this study were modestly increased compared with what would be expected for chemotherapy alone despite using an ipilimumab dose of 10 mg/kg that was of interest at the time the study was designed. There were cases of colitis and endocrinopathies reported, as expected with ipilimumab therapy. Hypothyroidism, adrenal insufficiency, colitis, and other immune-related side effects may require chronic therapy effecting quality of life in early-stage lung cancer patients who receive immune therapy as part of their treatment regimen. No patient was unable to go to surgery because of adverse effects of neoadjuvant therapy, although two patients had surgery delayed because of diarrhea thought to be caused by ipilimumab. The major objective response rate of 58% after neoadjuvant platinum, paclitaxel, and ipilimumab compares favorably with the 41% objective response rate reported for the Southwest Oncology Group trial that also studied neoadjuvant carboplatin and paclitaxel in early-stage lung cancer (21). However, the sample size in our study is small, so it cannot be concluded that our results indicate that ipilimumab plus chemotherapy is more active than chemotherapy alone in early-stage NSCLC. It was not possible to compare the immune effects of ipilimumab in patients responding to versus resistant with neoadjuvant therapy because only two tumors progressed after three cycles of neoadjuvant therapy.

Highly standardized polychromatic flow cytometric assay platforms were used to profile both functional and phenotypic changes brought about by ipilimumab therapy. Given the small sample of 24 patients, our analysis is designed as a descriptive study, with the goal to validate our observations in a large cohort study. By far, the most profound early immunologic effects seen in this study following administration of ipilimumab were the significantly increased frequencies of highly activated T cells in the peripheral circulation. Both CD4<sup>+</sup> and CD8<sup>+</sup> cells expressing the activation markers ICOS, HLA-DR, and CTLA-4 increased dramatically following phased ipilimumab with chemotherapy. Increased expression of CD4<sup>+</sup> cells, but not CD8<sup>+</sup> cells, coexpressing PD-1 were also noted. Earlier studies in advanced metastatic melanoma patients treated with ipilimumab also noted increased frequencies of ICOS<sup>+</sup> CD4 and CD8 cells, and suggested that the magnitude of the increase might be predictive of a clinical response (22, 23). The stable frequency of CD4 and CD8<sup>+</sup> T cells before and after ipilimumab suggest that the increase in activation is not due to cell expansion, but rather the activation of preexisting T cells in the periphery.

In this study, the ICOS<sup>+</sup> cells were nearly exclusively contained within the CD28<sup>+</sup> subset of CD8<sup>+</sup> T cells, whereas the HLA-DR<sup>+</sup> cells appeared to be equally distributed among both CD28<sup>+</sup> and CD28<sup>–</sup> subpopulations. Interestingly, a recent murine study demonstrated that the promotion of the CD8<sup>+</sup> T-cell response, after PD-1 blockade, is dependent on CD28 (16). In the same study, the proliferating CD8<sup>+</sup> T cells found in the blood of NSCLC patients, following PD-1–targeted therapy, were predominantly CD28<sup>+</sup>. CD28 expression has been demonstrated to decrease with age consequently resulting in a dampened immune response (24). Interestingly, the loss of CD28 expression may be prevented or even reversed using cytokines IL12 or IL21 (25, 26). While we do not suggest that CD28 is a predictive biomarker for immunotherapy response due to the small sample size, CD28 expression may be a worthwhile pharmacodynamic biomarker to evaluate in a large cohort study to identify patients who will benefit from immunotherapy.

Similar immune profiling was performed on the tumor microenvironment of all seven resected tumors available for study. Once again, high frequencies of CD4<sup>+</sup> and CD8<sup>+</sup> T cells expressing the activation markers ICOS, HLA-DR, CTLA-4, and PD-1 were observed. Overall, the frequencies of activated T cells within the tumor microenvironment were notably higher than those of their counterparts in the peripheral circulation. Unfortunately, unlike the available PBMC samples, we did not have pretreatment tumor samples available for immune profiling and, therefore, could not assess the relative contribution of ipilimumab therapy to the post-treatment activation status of the T cells populating the tumor microenvironment. Also, the tumors studied for immune phenotyping were only those tumors that could be resected and had excess tumor after neoadjuvant therapy, thus representing a selected subset of early-stage NSCLC.
Previous studies in advanced melanoma patients receiving ipilimumab therapy revealed that anti–CTLA-4 treatment potentiated CD4+ and CD8+ T-cell responses in the peripheral circulation against NY-ESO-1, MART-1, and gp100 (27). Using our highly standardized intracellular cytokine staining (ICS) assay, we found baseline anti-TAA reactivities in a total of 4 patients against MAGE-A3, survivin, or PRAME, 3 of the most common TAA expressed among non–small cell lung tumors (28, 29). In contrast with the melanoma studies, we failed to demonstrate any potentiation of preexisting TAA responses following ipilimumab therapy. Furthermore, we saw no evidence of the development of de novo anti-TAA responses during or after ipilimumab therapy. These differences could most likely be due to differences in the natural history of anti-TAA responses in melanoma versus NSCLC patients or the study of advanced stage (melanoma) versus early-stage NSCLC patient populations. We also failed to detect anti-TAA reactivities in any of the seven available tumor resection samples. Unfortunately, there were no tumor samples available for any of the 4 patients who had detectable anti-TAA responses in their PBMCs.

Tregs and MDSCs are seen as formidable obstacles to most immunotherapeutic strategies and have been previously studied in the context of ipilimumab therapy in advanced melanoma. Tarhini and colleagues (27) reported a significant increase in circulating Tregs that was associated with improved progression-free survival, whereas Treg levels within the tumor microenvironment were significantly reduced. In this study, we did not observe significant changes in the frequencies of circulating Tregs following ipilimumab therapy. CTLA-4 blockade has been demonstrated to deplete intratumoral Tregs through Fc receptor–mediated ADCC (30); however, the Treg levels among the seven tumors were higher and more highly variable than in PBMCs. Once again, in the absence of pretreatment tumor samples, we are unable to adequately assess the effect of therapy on Treg frequencies within the tumor microenvironment of NSCLC patients. MDSC frequencies were the focus of a previous study of ipilimumab treatment of advanced melanoma patients (20). This group reported that advanced melanoma patients with baseline PBMC levels of MDSC (defined as lin−CD14+HLA-DRlow/neg) less than 14.9% had a significantly increased likelihood of prolonged OS following ipilimumab therapy. Those patients with greater MDSC levels were far less likely to benefit from ipilimumab therapy. Thus, baseline circulating MDSC levels may represent a valuable predictive biomarker to identify patients who will most benefit from ipilimumab therapy. Of the 24 patients enrolled in the present NSCLC study, only 2 had MDSC levels >15%, and neither of them was classified as having progressive disease. Once again, the lower levels of MDSC in the current study could simply be a reflection of the earlier stage of disease that we are studying or differences in the biology of melanomas versus NSCLC. In a comprehensive study of 123 immune subsets following avelumab (anti–PD-L1 mAb) in patients with solid tumors, PD-L1 blockade had no effect on any of the 123 immune subsets in the peripheral blood, including Tregs and MDSCs (31). Observations in the peripheral blood between CTLA-4 and PD-L1 blockades differ because their function is site-specific. Anti–CTLA-4 blockade is mainly involved during initial T-cell priming in lymphoid tissues, whereas anti–PD-1/PD-L1 impacts the interaction of PD-1 and PD-L1 in the tumor microenvironment where PD-L1–expressing tumor cells are located (32–34).

This study did not meet the primary endpoint of detecting an increase in circulating T cells with specificities against TAA from 0% of subjects before therapy to 20% of subjects after neoadjuvant chemotherapy plus ipilimumab. Instead, we discovered that almost 20% of patients on the study had blood T cells with specificity against survivin, MAGE-A3, or PRAME at baseline, and ipilimumab did not increase the number of cases. Ipilimumab, but not chemotherapy alone, caused dramatic activation in blood CD4+ and CD8+ T cells, but did not have a marked effect on blood Tregs or MDSCs. These results suggest that the activation of T cells observed in this study with ipilimumab may be necessary but not sufficient by itself for a therapeutic immune effect in a subset of NSCLC, because ipilimumab alone did not improve survival when added to chemotherapy and the addition of ipilimumab to nivolumab appears to increase the number of durable responses in NSCLC (13). We were able to isolate variable but sufficient numbers of viable and functional immune cells from early-stage lung cancers after neoadjuvant immune therapy to perform flow cytometry analysis. Finally, much of what we know about the immunologic effects of ipilimumab therapy has been gleaned from studies conducted in the context of advanced malignant melanomas. Great care must be taken in attempting to extrapolate those findings to other tumor immunotherapy settings, as exemplified by our current studies of early-stage NSCLC patients. The data from this study will contribute to the understanding of how ipilimumab may be influencing therapeutic efficacy in combination immunotherapy for NSCLC. Thus, an understanding of immunotherapeutic effects in the context of early treatment becomes an important objective. Our current neoadjuvant study is extending immune profiling to studying neoadjuvant PD-1 checkpoint therapy in early-stage NSCLC. It is hoped that the observations reported herein will contribute to the development of an immune-based rationale for future combination immunotherapies in NSCLC patients.
