EPIDEMIOLOGY AND POLICY

How Will Alcohol Sales in the UK Be Affected If Drinkers Follow Government Guidelines?

Abstract — Aims: The proportion of alcohol consumption that is above government guidelines (‘risky drinking’) has been estimated in several countries, suggesting that reductions in risky drinking would lead to significant declines in total alcohol consumption. However, this has not previously been conducted transparently in the UK. Furthermore, existing studies have under-explored the importance of several methodological decisions, as well as not closely examining the meaning of these figures for debates on ‘corporate social responsibility’ (CSR). Methods: Secondary analysis of the amount of alcohol consumption above various government guidelines in four British datasets for 2000–2002: the National Diet and Nutrition Survey; the General Household Survey; Smoking, Drinking and Drug Use among Young People; and the March 2002 ONS Omnibus Survey. Results: Risky drinking accounts for 55–82% of the total consumption by 18- to 64-year-olds, depending on the definition of risky drinking used. If only alcohol above the government guidelines is counted, this falls to 22–47%. Consumption by underage drinkers accounts for 4.5% of the total consumption, while consumption by drink-drivers accounts for 0.5–8% depending on the assumptions made. Conclusions: Methodologically, the study shows that at least two decisions have considerable importance: the definition of risky drinking used and whether we count all drinking (as in most previous studies) or only drinking above guidelines. Substantively, these studies do not directly show that drink companies’ profitability would be affected by declines in risky drinking. Nevertheless, they are valuable for present debate in themselves and form the basis of a more complex analysis of alcohol CSR.

INTRODUCTION

Despite the existence of conditions for which the risk increases with any level of alcohol consumption, many governments have decided to issue government levels for ‘sensible’ drinking (ICAP, 2003) to provide help for citizens faced with a complex array of epidemiological evidence. Rather than looking at the lowest-risk level of alcohol consumption (White et al., 2002), the guidelines try and decide on an acceptable level of risk—a threshold that requires judgement as well as evidence, with the most sophisticated recent attempt in Australia suggesting a cut-off of a 1 in 100 lifetime chances of dying from an alcohol-attributable cause (Rehm et al., 2008; Australian Government NHMRC, 2009). In the UK, these guidelines were first clearly defined in 1992 after more than a decade of discussion (Department of Health, 1995), and numerous reports investigated the proportion of drinkers who drink above the guideline level.

However, no peer-reviewed studies in the UK have investigated the proportion of alcohol consumption that is above the government guidelines (Department of Health (2008), p. 12, refers to an internal estimate without explaining the methodology). This contrasts with recent studies in Canada (Stockwell et al., 2005), the United States (Foster et al., 2006) and Australia (Stockwell et al., 2008), as well as studies looking at the proportion of alcohol consumed by underage drinkers (Foster et al., 2003; Doran et al., 2009). These all suggest that reductions in the level of risky drinking would lead to (often significant) declines in the total sales of alcoholic drinks (‘sales’ here refers to the amount rather than the value of alcohol sold; see the Discussion section). Several public health professionals have also used this—alongside earlier evidence on the skewed nature of the distribution of drinking (Lemmens et al., 2001)—within debates on the role of alcoholic drinks’ companies (see below).

Even where studies have been conducted, the sensitivity of the results to assumptions and methods has been under-explored. Only one recent study has looked at the importance of different versions of government guidance, finding these significantly affect the results (Stockwell et al., 2005). Similarly, the results from different surveys within the same country are rarely compared (Foster et al., 2006). Finally, and most importantly, none of the published papers discuss whether we should include all risky drinking, or only risky drinking above the guideline levels.

This study therefore estimates the proportion of consumption accounted for by risky drinking in the UK and also makes three contributions to the wider use of such figures. Firstly, the study considers the importance of various assumptions simultaneously. Secondly, the study demonstrates the use of bootstrapped confidence intervals for these estimates. Finally, the study discusses the meaning of these figures in the context of wider debates on ‘corporate social responsibility’ (CSR) among drinks companies.

METHODOLOGY

To estimate the share of total alcohol consumption that is accounted for by risky drinking, two methodological decisions first need to be made: how to define ‘risky drinking’ and which parts of this risky drinking should be counted.

Defining ‘risky drinking’: This study considers three definitions of risky drinking taken from government guidelines.

1. The main definition follows the current ‘sensible drinking message’ that drinkers should not regularly exceed 3–4 units/day (men) or 2–3 units/day (women), a unit being 8 g/10 mL of pure alcohol. In practice, this is operationalized as ≤4 (men)/≤3 (women) units/day (PMSU, 2004, 2008, 2004, 2006; Australian Government NHMRC, 2009).

---

p. 11)—noting that this ignores the suggested 1–2 days per week of non-drinking (Goddard, 2001, p. 14).

2. Before 1995, the government guidelines were based on weekly rather than daily limits of 21 (men)/14 (women) units. These were still used by the 2004 Alcohol Strategy as a definition of ‘moderate to heavy drinking’ (PMSU, 2004, p. 11).

3. Drinking relatively large amounts of alcohol on single occasions—‘binge-drinking’—is associated with particularly high risks of harm (Anderson and Baumberg, 2006, chapter 4). While there is no NHS definition of binge-drinking, the Prime Minister’s Strategy Unit defined it as more than twice the current daily guidelines; i.e. >8 (men)/>6 (women) units/day (PMSU, 2004, p. 11).

This study also looks at the share of consumption involved in two other aspects of risky drinking: underage drinking and drink-driving. The definitions of these are more straightforward as all consumption in these situations can be considered risky, but the way of estimating these is discussed in more detail below.

**Counting risky drinking:** Among researchers conducting similar studies, there has been a debate about whether researchers should count all risky drinking or only drinking that is actually above the guidelines. For example, if risky consumption for men is defined as >4 units/day, then the 5 units/day drunk by a given man could be seen as either 5 units of risky drinking (the entire consumption) or only 1 unit (the consumption above the guidelines). This study conducts estimates under both assumptions, to enable us to examine their effects (this also aids comparability with previous studies).

**Data sources**

Using the Institute of Alcohol Studies’ Data Map—a publicly available resource for secondary analysis on alcohol, available from www.ias.org.uk—it became clear that no single survey contained data on daily as well as weekly drinking, in the full age range of the population, and including data on drink-driving behaviour. It was therefore decided to conduct estimates using several separate surveys from a single period, 2000–2001. These surveys are briefly described below and in Table 1; further information is available in online Appendix 1. Readers wishing to replicate the analysis or look for further detail on the data-cleaning process can access the full Stata code for this study from the author’s web-page at http://sticerd.lse.ac.uk.

The main survey used in this analysis is the National Diet and Nutrition Survey (NDNS), as it is one of the few surveys to ask about daily as well as weekly consumption. However, NDNS does not cover the full age range of the drinking population, hence the General Household Survey (GHS) was used for older drinkers and 16- to 18-year olds based on a standard quantity–frequency measure for each of six types of alcoholic drink (see online Appendix 1 for details). For the ages covered in both surveys, this also allows us to compare average consumption assessed via two methods: a 7-day diary (NDNS) versus an interview-based quantity–frequency recall of average drinking behaviour over the past 12 months (GHS). While 7-day measures are not generally recommended for alcohol surveys as they may not be a good guide to an individual’s usual consumption (Stockwell, in press, p. 58), 7-day diaries may be slightly better at capturing unusual consumption that is ignored when people are asked about how much they ‘usually drink’ (although not to the level of past-day reports; Greenfield and Kerr, 2008). They may therefore be more suited to estimating the proportion of alcohol consumed above daily and weekly thresholds at the population level.

To get information on 11- to 15-year-old drinkers, the Smoking, Drinking and Drug Use among Young People (SDD) survey was used. The mean alcohol consumption in each single-year age group from SDD and GHS and the 18+ age group from GHS was multiplied by age-specific population data for 2001, taken from National Statistics estimates (see Table 1). Finally, the March 2002 ONS Omnibus survey is the closest survey to this time period that contains data on both self-reported drinking and drink-driving. This includes separate questions on the self-reported past-12-month frequency of (i) any drinking before driving and (ii) driving over the legal drink-driving limit, which may be considered as upper and lower limits. For each, the share of alcohol consumption on such occasions was estimated in two ways. Firstly, it was assumed that on each reported drink-driving occasion, people drank an average amount (calculated from their personal average). Secondly, it was assumed that on each reported drink-driving occasion, people drank as much as the maximum that they reported drinking before...
often not included them (e.g. Stockwell et al. 2008). Where they have been included (Greenfield and Rogers, 1999; Foster et al., 2006), these appear to be based on the survey-design-adjusted CI for the mean consumption in those drinking over government guidelines. This is a different quantity than their share of consumption, and consequently the estimates do not take into account sampling error around the proportion of people consuming over government guidelines.

This study instead uses non-parametric bootstrap estimates to create confidence intervals (Efron and Tibshirani, 1993; Carpenter and Bithell, 2000). These were done using the ‘bootstrap’ command in Stata v9.0, with 2000 replications and using the ‘bca’ option to provide BCa estimates as recommended by Efron and Tibshirani. However, because the estimates for underage drinking use three different surveys, it was not possible to produce bootstrapped confidence intervals for these estimates.

RESULTS

Main results—counting all drinking

The main NDNS results using the conventional method of counting all drinking are shown in the third column of Table 2. The share of total alcohol consumption by 18- to 64-year olds accounted for by risky drinking ranged from 55% for binge-drinking to 82% for the current sensible drinking guidance. Given that NDNS only includes 18- to 64-year olds, GHS was used to look at the implications of including a full adult age range for the weekly definition of risky drinking (the more restrictive daily definition not being available in GHS). Table 3 shows that restricting the age range within GHS increases the share of consumption accounted for by risky drinkers—unsurprisingly given that those over 65 are less likely than younger drinkers to drink heavily, although the extent of this reduction is generally small.

Calculating confidence intervals

While the estimates are straightforward, producing confidence intervals (CIs) for them is more difficult as no formal mathematical expression is available, and previous studies have therefore often not included them (e.g. Stockwell et al., 2008). Where they have been included (Greenfield and Rogers, 1999; Foster et al., 2006), these appear to be based on the survey-design-adjusted CI for the mean consumption in those drinking over government guidelines. This is a different quantity than their share of consumption, and consequently the estimates do not take into account sampling error around the proportion of people consuming over government guidelines.

Table 2 shows the results from the drink-driving estimates, based on the occasions that people reported they drove after drinking. There are two measures of drink-driving behaviour and two different assumptions for each. Method 1 assumes that drink-drivers drank their personal average consumption; for example, under the current sensible drinking guidelines, risky drinking accounts for 46.6% rather than 82.3%. The differences will be greater where the threshold for risky consumption is highest (it is consumption between zero and the guideline level that is different in the two methods). As a result, the difference is greatest for the binge-drinking definition (from 54.7% to 22.3%) as this has the highest threshold. The impact of looking at the full age range in Table 3 is similar if smaller than that described above.

Underage drinking

At the time the research was first undertaken, there was no guideline for risky consumption in underage drinkers. While draft guidance has been published more recently (Chief Medical Officers, 2009), it seems reasonable to treat all underage drinking as counter to government advice given its illegality. The results are shown in Table 4. In total, underage drinking accounts for 4.5% of consumption, this being primarily among 15- to 17-year olds rather than under 15-year olds.

Main results—only counting drinking above the guidelines

If we only count drinking above the guidelines, we obtain the estimates in the fourth column of Table 2. These estimates are considerably lower than the estimates based on all risky drinking; for example, under the current sensible drinking guidelines, risky drinking accounts for 46.6% rather than 82.3%. The differences will be greater where the threshold for risky consumption is highest (it is consumption between zero and the guideline level that is different in the two methods). As a result, the difference is greatest for the binge-drinking definition (from 54.7% to 22.3%) as this has the highest threshold. The impact of looking at the full age range in Table 3 is similar if smaller than that described above.

Drink-driving

Table 5 shows the results from the drink-driving estimates, based on the occasions that people reported they drove after drinking. There are two measures of drink-driving behaviour and two different assumptions for each. Method 1 assumes that drink-drivers drank their personal average consumption level before driving, while Method 2 assumes that drink-drivers...
drank their maximum reported drinking-before-driving level in the past 12 months. Unsurprisingly, Method 1 produces higher estimates of the proportion of total consumption that is drunk on drink-driving occasions than Method 2; the Method 2 figures would seem likely to be more accurate, but given likely underreporting in the drink-driving data (see the Limitations section below) the Method 1 results are included as an upper bound.

If we then compare the two self-report measures of drink-driving, we see that the share of consumption drunk before driving at all is much greater than the share of consumption drunk before breaking drinking laws. This is unsurprising; the former is an upper bound of the true figure (as it includes legal drinking-before-driving) while the latter is a lower bound (due to social desirability effects and lack of knowledge of the law). Even so, the size of the difference is perhaps surprisingly large (4.2–8.0% versus 0.5–1.0%).

**LIM I T AT I O N S**

There are several limitations to the estimates presented here. Firstly, the government guidelines differ from the absolute lowest-risk level of alcohol consumption in the UK (White et al., 2002) (the age-specific lowest-risk level of consumption at ages 16–24, 25–34, 35–44, 45–54, 55–64, 65–74, 75–84 and 85+, respectively, estimated to be 0, 0, 2, 5, 7, 8, 8, 8 units/week (men) and 0, 0, 0, 1, 2, 3, 3, 3 units/week (women)). Were we to use this definition, nearly all of the alcohol consumed in the UK would be involved in risky consumption, however calculated. For example, if risky drinkers instead drank the absolute lowest-risk amount, total consumption would decline by 91.7% (95% bootstrapped CI 90.9–92.5%). However, this ignores the difference between any risk and acceptable risk; the White et al. figures also do not account for drinking patterns.

Secondly, the drink-driving data appear to be unreliable. For example, of those reporting very frequent drink-driving, many report drinking more often than they report drinking per se. Simultaneously, nearly half of those drinking 10+ units on the last drink-driving occasion said they were not over the legal limit when they drove, suggestive of (predictable) social desirability effects or ignorance of the law. The drink-driving estimates are therefore not robust and only give indicative figures as to the likely share of consumption associated with drink-driving.

Third, it is well established that most surveys of alcohol consumption find that less alcohol has been drunk than has been recorded as sold. The volume of alcohol reported in surveys is usually 40–60% of total consumption (Stockwell et al., 2005), and previous similar studies have accepted low coverage rates of 30–40% (Foster et al., 2003; Miller et al., 2006). In this study, 57–60% of alcohol consumption is reported in the surveys (see Table 1). To the extent that under-reporting is greater among heavier drinking respondents (Goddard, 2008) and heavy drinkers are less likely to respond (Bloomfield et al., 2003), there will be an underestimate in the share of consumption associated with risky drinking.

There are two other minor limitations of the research. The survey of young people (SDD) is unweighted and restricted to England, and will therefore produce biased estimates for Great Britain as a whole. However, consumption at ages 11–15 is very low (as shown in Table 4); hence, even relatively large biases will have small effects on the overall results. The other minor limitation is that the NDNS data are diary-based unlike the rest of the data that are interview-based. In particular, interview-based data represent people’s reports of their average consumption find that less alcohol has been drunk than has been recorded as sold. The volume of alcohol reported in surveys is usually 40–60% of total consumption (Stockwell et al., 2005), and previous similar studies have accepted low coverage rates of 30–40% (Foster et al., 2003; Miller et al., 2006). In this study, 57–60% of alcohol consumption is reported in the surveys (see Table 1). To the extent that under-reporting is greater among heavier drinking respondents (Goddard, 2008) and heavy drinkers are less likely to respond (Bloomfield et al., 2003), there will be an underestimate in the share of consumption associated with risky drinking.

The survey of young people (SDD) is unweighted and restricted to England, and will therefore produce biased estimates for Great Britain as a whole. However, consumption at ages 11–15 is very low (as shown in Table 4); hence, even relatively large biases will have small effects on the overall results. The other minor limitation is that the NDNS data are diary-based unlike the rest of the data that are interview-based. In particular, interview-based data represent people’s reports of their average consumption in the past 12 months, and unusually heavy drinking occasions will be missed out from these self-reports. However, comparing NDNS and GHS data for 19- to 64-year olds in Table 3, the effect seems relatively small.

**DISCUSSION**

**Comparisons to other studies**

While different studies internationally have used different definitions of risky drinking and are based on different survey
methodologies, it is possible to undertake a cautious comparison between studies to set the present results in context. These comparisons can account for the differences in 'standard drink' sizes between countries, but there will be unaccounted-for differences between standard drinks and the actual drink size poured in the country (Stockwell et al., 2008). Beginning within the UK, it is reassuring that the estimates are close to the Department of Health (2008, p. 12) figures. They estimate that drinking above the government weekly guidelines accounted for 76% of UK alcohol consumption (in 2006 using updated conversion factors), which is relatively close to the 69% estimated here (for 2001 using GHS and the old conversion factors).

Looking internationally, the limited comparison available suggests the UK figures are higher than the estimates for the United States and Canada but roughly comparable to those from Australia. This is most clearly apparent for the estimates counting all drinking: 46% of alcohol consumption in the United States (Foster et al., 2003) and 61% in Canada was above 3.4 UK units/day (Stockwell et al., 2005), compared to 82% of consumption by 18- to 64-year olds being above 4 (men)/3 (women) units/day in the UK. Similarly, 42% of Canadian consumption was above 6.8 (men)/5.1 (women) UK units/day in the UK. This is most clearly apparent for the estimates counting all drinking: 46% of alcohol consumption in the United States (Foster et al., 2003) and 61% in Canada was above 3.4 UK units/day (Stockwell et al., 2005), compared to 82% of consumption by 18- to 64-year olds being above 4 (men)/3 (women) units/day in the UK. Similarly, 42% of Canadian consumption was above 6.8 (men)/5.1 (women) UK units/day in the UK. This is most clearly apparent for the estimates counting all drinking: 46% of alcohol consumption in the United States (Foster et al., 2003) and 61% in Canada was above 3.4 UK units/day (Stockwell et al., 2005), compared to 82% of consumption by 18- to 64-year olds being above 4 (men)/3 (women) units/day in the UK. Similarly, 42% of Canadian consumption was above 6.8 (men)/5.1 (women) UK units/day in the UK.

**The impact of different assumptions**

Of the three methodological decisions mentioned in the Introduction section, this study has shown two of these matter considerably. Firstly, higher government guidelines reduce the amount of consumption accounted for by risky drinking. This is unsurprising in itself but perhaps more so in degree; for example, 55% of all consumption is accounted for by government-designated binge-drinking, compared to 82% if risky drinking is defined as the government’s official sensible drinking message. These differences are particularly large if we only count drinking above the guidelines, in which case binge-drinking accounts for 22% of consumption while the sensible drinking message accounts for 47%.

Secondly, both this study and Foster et al. (2003) show that it matters whether we count all drinking or just drinking above guidelines. Risky drinking here consistently accounts for a majority of sales if we count all drinking (55–82%) but only a minority if we only include drinking above the guideline levels (22–45%). Finally, the results did not change significantly between a diary-based (NDNS) and survey-based (GHS) methods, suggesting that examining the same estimates from different surveys is non-essential.

**Implications**

Finally, does this study purport to show—like other studies have claimed (Hawks, 1993; Anderson, 2003, p. 4)—that ‘it is not in the alcohol industry’s financial interest to voluntarily enact strategies to reduce underage or adult excessive drinking’ (Foster et al., 2003, p. 994)? In fact, these figures do not directly show a conflict of interest for two reasons.

Firstly, the figures relate to total sales by volume rather than total sales by value. Other studies have attempted to estimate the value of sales by risky drinkers (Foster et al., 2003, p. 992; and confirmed by Kerr and Greenfield (2007)). Accounting for this would be possible but would require special DEFRA permission to use the special access version of the Expenditure and Food Survey. In the meantime, we can only say that the proportion of spending by risky drinkers will be lower than the proportion of consumption by them.

Secondly, the figures ignore other reasons why it would be in drink companies’ ‘enlightened self-interest’ to reduce risky drinking. It is these reasons that enable the companies on the board of the International Center for Alcohol Policies to claim that ‘we take strong exception with the assertion that “there is a fundamental conflict” between commercial interests and the public health goal. . . . Our operators. . . see no contradiction between these goals’ (Leverton et al, 2000, p. 1430). This is not to say that such a view is necessarily justified, but rather that these other reasons must themselves be empirically considered—and these are covered in detail elsewhere (Baumberg, in press).

Nevertheless, the results such as those presented here are valuable figures to add to the public debate in their own right (Tom Greenfield, personal communication on 27 January 2009)—although they can be framed differently from different perspectives. Drinks companies could emphasize that less than half of 18- to 64-year olds’ consumption is accounted for by risky drinkers, if we only look at the consumption that is actually above the guidelines. Consumption due to underage drinking (4.5%) and drink-driving (0.5–8.0%, probably closer to the former) does not change this conclusion substantially. This is lower than the estimates in previous studies and reflects the importance of looking only at consumption above the guidelines, a methodological assumption that drinks companies could argue is justified given their focus on getting drinkers to ‘drink responsibly’ rather than to stop drinking per se.

At the same time, CSR critics could argue that even in this situation, there is a sizeable amount of consumption (at least 22–47%) accounted for by risky drinkers. If we assume that this would only be marginally affected if we looked at the value rather than volume of sales—which may or may not be true—this means that a very strong ‘enlightened self-interest’ motive is required for drinks companies to have a reason to reduce risky drinking. Furthermore, there are other occasions when it may be more sensible to look at all consumption, in which case the share of consumption in risky drinking rises to 55–82%. Some effective policy options may be more likely to turn risky drinkers into non-drinkers, or to have an equivalent impact by reducing consumption among the entire population. And as Tim Stockwell has pointed out (in a personal communication on 25 January 2009), for a person drinking over the guidelines it is not possible to say which of the drinks they consume are risky and which are not; essentially they are all involved in the risky consumption.

In conclusion, this paper’s contribution has been partly methodological and partly empirical. Methodologically, the study has shown the sensitivity of estimates of the consumption accounted for by risky drinkers to different definitions of risky drinking and different counterfactuals, as well as introducing bootstrap methods to calculate confidence intervals for the estimates. Empirically, this paper has transparently estimated for
the first time the consumption accounted for by risky drinkers in the UK, and better examined the implications of these results for policy. From this, we have the necessary starting point for a more complex analysis of the phenomenon of alcohol CSR, an analysis that is developed elsewhere (Baumberg, in press).

Acknowledgements — Many thanks to Tom Greenfield and Tim Stockwell for helpful discussions on some of the issues surrounding this topic, to Andrew McNeill, Russell Ben-neits and Rachel Seabrook for comments on initial drafts, to the editor and an anonymous reviewer for a number of helpful suggestions, and to the Institute of Alcohol Studies for agreeing to fund this work. This research was based on the General Household Survey, 2000–2001 (produced by the Social Survey Division of the Office of National Statistics (ONS), and sponsored by the ONS, Department of Health, Department of the Environment, Transport and the Regions, Department for Culture, Media and Sport, Department of Social Security, Department for Education and Employment and Inland Revenue), the National Diet and Nutrition Survey: Adults Aged 19 to 64 Years, 2000–2001 (produced by the Social and Vital Statistics Division of the ONS and Food Standards Agency (FSA) in collaboration with the MRC Resource Centre for Human Nutrition Research, and sponsored by the FSA and Department of Health), the ONS Omnibus Survey, March 2002 (produced by the Social Survey Division of ONS and sponsored by the Department of Health, Department of Customs and Excise, Home Office Alcohol Research Unit, ONS Population and Demography Division, Department for Work and Pensions, and ONS So-cial Survey Division), and Smoking, Drinking and Drug Use among Young People, 2001 (produced by NatCen and NFER, sponsored by the Department of Health). All data were supplied by the UK Data Archive (Study Numbers are given in Table 1). All data are Crown copyright material reproduced with the permission of the Controller of HMSO and the Queen’s Printer for Scotland, except the modules of the ONS Omnibus Survey for whom copyright resides with the module sponsors.
