\textbf{ABSTRACT}

An internal shock model is proposed to interpret the radio to infrared (IR) emission of the compact jets observed in the hard spectral state of X-ray binaries. Assuming that the specific bulk Lorentz factor of the jet at its base varies with a flicker noise power spectrum [i.e. $P(f) \propto 1/f^{3}$], we estimate the energy dissipation profile along the jet and the resulting partially self-absorbed synchrotron emission. For this type of velocity fluctuations, and a conical jet geometry, the shock dissipation at large distance from the black hole balances exactly the adiabatic losses. This leads to a flat radio to IR spectral energy distribution similar to that observed in compact jets.

\textbf{Key words:} accretion, accretion discs – black hole physics – radiation mechanisms: non-thermal – relativistic processes – shock waves – X-rays: binaries.

\section{INTRODUCTION}

Internal shocks caused by fluctuations of the outflow velocity are widely believed to power the multiwavelength emission of jetted sources such as γ-ray bursts (Rees & Meszaros 1994; Daigne & Mochkovitch 1998), active galactic nuclei (Rees 1978; Spada et al. 2001) or microquasars (Kaiser, Sunyaev & Spruit 2000; Jamil, Fender & Kaiser 2010). Internal shock models usually assume that the shock can be discretized into homogeneous ejecta. Those ejecta are injected at the base of the jet with variable velocities and then propagate along the jet. At some point, the fastest fluctuations start catching up and merging with slower ones. This leads to shocks in which a fraction of the bulk kinetic velocity of the shells is converted into internal energy. Part of the dissipated energy goes into particle acceleration, leading to synchrotron and also, possibly, inverse-Compton emission.

Here, we will focus on the applicability of this model to the steady compact jets observed in the hard X-ray spectral state of black hole and neutron star binaries. These sources have an approximatively flat spectral energy distribution (SED) extending from the radio to the mid-infrared (mid-IR; e.g. Fender et al. 2000; Corbel & Fender 2002; Chaty et al. 2003). These flat spectra are usually ascribed to self-absorbed synchrotron emission from conical compact jets (Blandford & Königl 1979) under the assumption of continuous energy replenishment of the adiabatic losses. The compensation of these energy losses is crucial for maintaining this specific spectral shape (Kaiser 2006), and this can possibly be achieved through internal shocks. Recently, however, Jamil et al. (2010) developed an internal shock model for the emission of jets in X-ray binaries, and concluded that energy dissipation only through internal shocks is not enough to produce a flat SED.

In fact, this result is not very surprising. Let us consider a jet with uniform time-averaged bulk Lorentz factor $\gamma = 1/\sqrt{1-\beta^{2}}$ and a section of the jet consisting in a cylindrical shell of radius $R$ and height $H \ll R$. This shell propagates downstream, so that at a time $t$, measured in the comoving frame, its position along the jet is $z = \gamma \beta c t$. The function $R(t)$ defines the jet geometry. For simplicity, in this Letter we will consider only conical jets: i.e. $R = R_{0} + z \tan \phi$, where $\phi$ is the half-opening angle of the jet and $R_{0}$ is the radius of the jet at its base. The shell has a specific internal energy $\dot{\epsilon}$ (measured in the comoving frame). The energy losses are usually dominated by adiabatic expansion, i.e. the pressure work exerted by the shell against the external medium as it travels downstream and expands:

$$d\dot{W} = P d\dot{V} = (\gamma_{s} - 1) m \dot{\varepsilon} \frac{d\dot{V}}{\dot{V}} \simeq \frac{2m \dot{\varepsilon}}{3} \frac{dR}{R},$$

(1)

where $P$ is the total pressure in the shell (including magnetic pressure), $\dot{V}$ is its comoving volume, $m$ its mass and $\gamma_{s}$ is the effective adiabatic index of the flow. For simplicity, it is assumed here that all the components of the flow (thermal particles, relativistic particles, magnetic field, etc.) have the same adiabatic index corresponding to that of a relativistic gas (i.e. $\gamma_{s} = 4/3$). The last term of equation (1) is obtained neglecting the effects of possible longitudinal expansion. At large $z$, $R \simeq z \tan \phi$, and, in the comoving frame, the shell loses its specific energy at a rate:

$$\left. \frac{d\dot{\varepsilon}}{dt} \right|_{\text{ad}} = - \frac{2(\gamma_{s} - 1) \dot{\varepsilon}}{R} \frac{dR}{dt} \simeq \frac{2 \dot{\varepsilon}}{3\dot{R}}.$$

(2)

If, as required to reproduce the flat SED of compact jets, the adiabatic losses are fully replenished by some dissipative process, then \( \tilde{e} \) must be a constant. Equation (2) then implies that the replenishing mechanism must have a dissipation profile \( \propto t^{-1/3} \) over a long section of the jet. Usual internal shock models predict instead a dissipation profile scaling like \( t^{-5/3} \) (Beloborodov 2000) and therefore cannot compensate for the losses over a long section of the jet.

Nevertheless, most studies of the internal shock model so far, including that of Beloborodov (2000) and Jamil et al. (2010), have implicitly assumed that the Fourier power spectral density (PSD) of the velocity fluctuations injected at the base of the jet is flat (i.e. white noise). In fact, the energy dissipation profile of the internal shocks is very sensitive to the shape of the PSD of the velocity fluctuations. Indeed, let us consider a fluctuation of the jet velocity of amplitude \( \Delta v \) occurring on a time-scale \( \Delta t \). This leads to the formation of a shock at a downstream distance \( z \propto \Delta t / \Delta v \). In this shock the fraction of the kinetic energy converted into internal energy will be larger for larger \( \Delta v \). From these simple considerations we see that the distribution of the velocity fluctuation amplitudes over their time-scales (i.e. the PSD) is going to determine where and in what amount the energy of the internal shocks is deposited. In this Letter, instead of a white noise PSD, we will assume that the PSD of the injected fluctuations decreases with Fourier frequency like \( P(f) \propto 1/f \) (i.e. flicker noise). Such noise occurs in many physical, biological and economic systems (see e.g. Press 1978). In astronomy, it is observed in the solar activity (e.g. Ryabov et al. 1997) and, most notably, in the X-ray variability of X-ray binaries (see e.g. Gilfanov 2010). In Section 2, we show that shocks driven by this type of fluctuations can compensate exactly for the adiabatic losses in a conical geometry. In Section 3, we estimate the jet volume-filling factor. Then, in Section 4, we derive estimates for the predicted SED of the jet. Finally, in Section 5, these results are discussed in the context of black hole binaries (BHBs).

2 INTERNAL SHOCK DISSIPATION PROFILE

We assume that small, time-dependent fluctuations of the Lorentz factor are continuously injected at the base of the jet. The fluctuations depend on time \( t \) and have a Fourier power density spectrum \( S(f) = S_0 f^{-1} \) for frequencies ranging from \( f_1 \) to \( f_0 \). The initial variance of the injected fluctuations is, therefore,

\[
\gamma_{\text{rms}}^2 \equiv \int_{f_1}^{f_0} 2S(f)\,df = 2S_0 \ln \left( f_0/f_1 \right). \tag{3}
\]

We model the jet as a set of discrete homogeneous shells that are ejected with such variable velocities at time intervals \( \Delta t = (2\tilde{f}_0)^{-1} \). For simplicity, the mass of the ejecta is assumed to be a constant \( m_0 = 0.5P_I\Delta t/(\gamma - 1)c^2 \), where \( P_I \) is the total kinetic power of the two-sided jet. At injection, the centre of momentum of two neighbouring shells are separated by a distance \( \lambda_0 = \beta c \Delta t \). This length also corresponds to the smallest scale of the velocity fluctuations. As the ejecta propagate downstream, the fastest shells catch up and merge with slower ones. During this process of hierarchical merging the mass of the ejecta and their separation will increase \( \lambda(t)/\lambda_0 = m(t)/m_0 = K(t) \). This growth in length scale implies a damping of the fluctuations of frequencies higher than \( \tilde{f}_0/K \). As a consequence, the variance of the fluctuations decreases:

\[
\gamma_{\text{rms}}^2(K) = \int_{f_1}^{f_0/K} 2S(f)\,df = \gamma_{\text{rms}}^2 \cdot 2S_0 \ln \left( f_0/f_1 \right). \tag{4}
\]

The problem appears simpler when viewed in the frame moving with a Lorentz factor \( \gamma \). Throughout this Letter, the tilded quantities are measured in this comoving frame. In the limit of small-scale fluctuations, this frame coincides with the frame of the centre of momentum of the shells. In this frame, the average velocity of the shells is 0 and its rms amplitude is, to first order in \( \gamma_{\text{rms}}/\gamma \),

\[
\tilde{v}_{\text{rms}}(K) = \frac{\gamma_{\text{rms}}(K)c}{\gamma^2}. \tag{5}
\]

In the limit of low amplitude fluctuations, the velocities in the moving frame are non-relativistic. All of the kinetic energy of the shells is available for conversion into internal energy. We define the specific free energy of the system (i.e. available for dissipation) as \( \tilde{u}(K) = \tilde{v}_{\text{rms}}^2(K)/2 \). Combining equations (4) and (5) we see that the specific free energy decreases as the scale of the fluctuations increases:

\[
\frac{d\tilde{u}}{dK} = -\frac{S_0c^2}{K\gamma^2\beta^2}. \tag{6}
\]

The fluctuations of scale \( K \) collide and merge after travelling during a time

\[
\tilde{t}(K) = \gamma\tilde{\lambda}/\Delta \tilde{v}, \tag{7}
\]

where \( \gamma \) is a factor of order of unity accounting effects of the longitudinal extension of the ejecta. It will be estimated in Section 3. \( \Delta \tilde{v} \) is the average (absolute) velocity difference between the merging shells. In the case of a linear variability process it can be estimated as

\[
\Delta \tilde{v}^2 = G^2(K)\frac{S_0c^2}{2\gamma^2\beta^2}, \tag{8}
\]

with

\[
G(K)^2 = 8 \int_{f_1}^{f_0/K} \left[ 1 - \cos(K\pi f/f_0) \right] f^{-1} \,df. \tag{9}
\]

In the limit \( K \ll f_0/f_0 \), the function \( G(K) \) is nearly constant:

\[
G(K) \simeq M = \left[ -8 \sum_{n=1}^{\infty} \frac{(-\pi/2)^n}{(2n)!(2n)} \right]^{1/2} \simeq 3.6. \tag{10}
\]

Then, combining equations (7), (8) and (10), we find that the growth of the fluctuations is linear, \( K = t/f_0 \), with a characteristic timescale

\[
\tilde{t}_0 = \sqrt{2}\gamma\tilde{\lambda}^2/\Delta \tilde{v}^2 f_0^{-1} \Delta \tilde{v}^{-1} S_0^{-1/2}. \tag{11}
\]

Then combining this with equation (6), we conclude that at times \( \tilde{t}_0 \ll t \ll \tilde{t}_0/f_1 \), the free energy is dissipated at a rate

\[
\frac{d\tilde{u}}{d\tilde{t}} = -\frac{S_0c^2}{\gamma^2\beta^2}. \tag{12}
\]

This scaling of the dissipation profile balances the adiabatic losses (equation 2), for

\[
\tilde{e} = \tilde{e}_1 = \frac{1}{(\gamma_1 - 1)}\frac{S_0c^2}{2\gamma^2\beta^2}. \tag{13}
\]

From equation (13), we can estimate the sound speed in the jet as \( \tilde{v}_s = \sqrt{\tilde{e}(\gamma_1 - 1)} \). Note that, since \( \tilde{e} \) also contains the magnetic energy, \( \tilde{v}_s \) represents in fact an upper limit on the true sound velocity. Using equations (8) and (10), we find the average Mach number of the colliding ejecta is at least \( \Delta \tilde{v}/\tilde{v}_s = M \gtrsim 3.6 \). Such supersonic collisions ensure that strong shock waves will be generated. The region of the jet with significant shock dissipation starts at a distance \( z_0 \simeq \gamma_1 \tilde{\lambda} \). Therefore, at \( z < z_0, \tilde{e} \simeq 0 \). At the other end of the jet, at distances \( z > z_1 = \tilde{z}_0 f_1/f_0 \), all the energy of the internal shocks has been dissipated, and the flow simply cools down through adiabatic...
losses: \( \dot{\varepsilon} \sim \dot{s}_{ls}(\Delta \gamma)\). In the range \( z_{ls} \), the specific energy of the flow is approximately uniform and is given by equation (13).

### 3 Longitudinal Extension of the Ejecta

The volume-filling factor of the colliding shells, \( f_v \), is defined so that the average length of a shell of separation \( \lambda \) is \( f_v \lambda \). If \( f_v \ll 1 \), the jet is constituted of thin colliding ’pancakes’, while for \( f_v = 1 \), the jet is a continuous flow. In principle, \( f_v \) depends on the properties of the shells at injection. However, \( f_v \) is also expected to depend on \( z \) (or \( \tau \)). Indeed, as the shells propagate and gain internal energy through shocks, they also expand under the effect of their own pressure. Here, as it is customary, we assume that this expansion occurs at the sound speed in the comoving frame \( \dot{v} \). For simplicity, we will consider that the shells expand in near vacuum, and therefore the adiabatic losses due to longitudinal expansion can be neglected (free expansion). Any pressure work done during this expansion can only be used to accelerate or compress neighbouring shells so that overall, this does not represent a loss of energy for the flow. We thus do not expect that taking these effects into account would change the results dramatically.

The shells can also undergo significant compression during shocks. When two shells are in the process of merging, the compression velocity is simply the difference of velocity of the two merging ejecta. During a collision, however, the compression lasts only for the time necessary for the shock to cross the shell, i.e. \( \Delta t = x_f \Delta \dot{v} \), where \( \Delta \dot{v} \) is the speed of the shock in the frame of the unshocked jet. Applying the jump conditions of Blandford & McKee (1976) and to first order in \( \Delta \dot{v} \), their equation (5) gives

\[
x^{-1} \sim \sqrt{1/4 + \gamma_\ast/2 + (\gamma_\ast/2)^2} = 7/6.
\]

Since the collisional time-scale is \( \sim \gamma \Delta \dot{v} \), the shells are compressed during a fraction \( \sim x_f \gamma \Delta \dot{v} \) of the time, and the time-averaged compression velocity is reduced to \( \dot{v}_{\text{comp}} \sim x_f \gamma \Delta \dot{v}/y \). The parameter \( y \) in equation (7) can be approximated as

\[
y = \frac{1 - f_v}{1 + 2 M^{-1}}.
\]

The numerator on the right-hand side of equation (15) accounts for the reduced distance between shells due to their longitudinal extension. The denominator corrects for the increased collision rate caused by the expansion velocity of the shells.

As shown in Section 2, the choice of a flicker noise implies that, at large \( z \), the expansion velocity is a constant and independent of \( f_v \). The compression velocity instead monotonically with \( f_v \). As a consequence the volume-filling factor evolves towards an equilibrium in which, on average, compression balances longitudinal expansion. This occurs for

\[
f_v \simeq [1 + x(1 + M/2)]^{-1} \simeq 0.3,
\]

independently of the parameters. In fact, the evolution of \( f_v \) is more complex, but in practice, assuming it is a constant, it turns out to be a good approximation. We will therefore set \( f_v = 0.3 \) and \( y = 0.5 \).

### 4 Spectral Energy Distribution

We now use a simple emission model to estimate the properties of the jet SED as a function of the amplitude and bandwidth of the Lorentz factor fluctuations. A fraction of the internal energy is in the form of relativistic electrons. For simplicity, we assume that the distribution of the electrons on their Lorentz factors \( \gamma_e \) is a power law: \( n(\gamma_e) = n_0 \gamma_e^{-p} \), with \( \gamma_e \) in the range \( \gamma_{\text{min}} \rightarrow \gamma_{\text{max}} \). The remaining fraction is in the form of magnetic field energy. The particle energy density is

\[
n_0 \dot{m} c^2 \gamma_e^{-p} \gamma_e^{2} d\gamma_e = n_0 \dot{m} c^2 \gamma_e^{2} d\gamma_e = \xi B^2 / 8 \pi,
\]

where \( \xi \) is the equipartition factor that we assume constant. The magnetic field energy density is

\[
B^2 / 8 \pi = \frac{\dot{\rho} \dot{v}}{1 + \xi}.
\]

As a consequence, in this regime, the magnetic field scales as \( B = B_0 R_0 / R \), where \( R_0 = z_0 \eta \tan \phi \), and

\[
B_0 = \frac{2 f_0 \dot{m} \dot{M}}{\gamma \eta \tan \phi} \left( \frac{P(\gamma \beta \gamma - 1)^{-1}}{\gamma(\gamma - 1)(1 + \xi)} \right) f_0 c^3.
\]

where \( \eta = 1 + R_0/(z_0 \tan \phi) \). This scaling holds approximately for \( r > R_0(R_0 > 1) \), where \( r = f_0/f_1 + 1 - n^{-1} \simeq f_0/f_1 \). At larger distances, i.e. \( R > rR_0 \), the magnetic field decays faster due to the absence of shock dissipation to balance the adiabatic losses.

The relativistic electrons emit synchrotron radiation. Their emissivity at a comoving photon frequency \( \nu \) is (Rybicki & Lightman 1979)

\[
\dot{J}_p = K \xi B (p+5/2) \nu^{-p(1-1)/2},
\]

where

\[
K_p = \frac{3 e^3}{16 \pi^2 m_e^2 c^4} \Gamma \left( \frac{3p + 19}{12} \right) \frac{12}{p + 1} \frac{p}{p-1} \Gamma \left( \frac{3p - 1}{12} \right)
\]

and \( \Gamma \) is the usual gamma function, \( m_e \) and \( e \) are the electron mass and charge respectively. This emission can be self-absorbed. The absorption coefficient is

\[
\alpha_v = K_e \xi B (p^2/3) \nu^{-p(4)/2}.
\]

The specific intensity at the surface of the jet is

\[
I_v = \frac{\dot{J}_p}{\alpha_v} (1 - e^{-\alpha_v \delta}).
\]

In the case of a conical jet in a steady state, making an angle \( \theta \) with the line of sight, the flux at an observed frequency, \( \nu = \delta \nu \), is

\[
F_\nu = \frac{f_0 \delta^2}{2 D^2 \tan \phi} \int_{R_0}^{\infty} R L_\nu(R) dR,
\]

where \( \delta = \sqrt{\gamma (1 - \beta \cos \theta)} \) is the Doppler factor and \( D \) is the distance to the source. In order to obtain analytical estimates of the observed SED we now assume that the magnetic field has the \( R^{-1} \) dependence given by equation (20) for \( R \) between \( R_0 \) and \( R_0 = rR_0 \), and \( B = 0 \) elsewhere. The SED can then be approximated as follows. At the highest frequencies the emission is optically thin and the spectrum is a power law \( F_\nu \propto \nu^{-(p-1)/2} \), while at the lowest frequencies the emission is optically thick \( F_\nu \propto \nu^{p/2} \). For \( p > 3 \), there is a range of intermediate frequencies, comprised between \( \nu_i \) and \( \nu_f \),
and $v_s$, in which the emission at a given frequency is a mixture of optically thick and thin emission from different regions of the jets. In this regime, the flux is independent of the photon frequency (see e.g. Kaiser 2006):

$$F_{\nu}(\nu) \approx -\Gamma(a) \alpha f_0 K_o R_5 B_0 \frac{\zeta\xi}{D^2 \tan(\phi(p + 4)K_o^{\alpha+4}g^a)},$$

where $a = -5/(p + 4)$. The observed turnover frequency, $v_{\nu}$, is at the intersection of the optically thin and flat asymptotic branches:

$$v_{\nu} \approx \delta \left( K_o R_5 B_0^{(p/2+1)} \right)^{2/(p+4)} \left[ \frac{r^{(1-p)/2} - 1}{(a + 1)\Gamma(a)} \right]^{2/(p+1)}.$$  

The observed frequency of transition to the low-frequency optically thick regime is given by

$$v_s \approx \delta \left( K_o R_5 B_0^{(p/2+1)} \right)^{2/(p+4)} \left[ \frac{r^{5/2} - 1}{a\Gamma(a)} \right]^{-2/5}.$$  

These analytical estimates have been tested against Monte Carlo simulations of the internal shock model with a code similar to that of Jamil et al. (2010). Fig. 1 compares the average SED given by the analytical formula to that obtained from a simulation with parameters corresponding to Cyg X-1 (see caption of Fig. 1 and Section 5). The main differences occur around and below $v_\nu$ when the self-similar approximation that we used in the analytical formulae breaks down. Also, unlike the simulation, the analytical model ignores the emission of from the jet at distance larger than $z_0$.

It is worth noting, however, that in order to obtain analytical estimates of the SED, we had to make several simplifications. First, equation (25) neglects the angular dependence of the optical depth; this is a good approximation only for systems with a large inclination. Then, we also assumed that the electron energy distribution is a pure power law and therefore neglected the effects of a thermal component in the electron distribution. We also neglected the effects of adiabatic cooling on the shape of the electron distribution. Simple estimates indicate that both effects will affect the SED only marginally. On the other hand, the effects of radiative cooling can be very strong in the region close to the base of the emitting region (see e.g. Chaty, Dubus & Raichoor 2011). These radiation losses, which we have neglected, affect predominantly the most energetics electrons, emitting in the optically thin regime, while the flat optically thick part of the SED is essentially unchanged (Zdziarski, Lubinski & Sikora 2012).

5 APPLICATION TO BLACK HOLE BINARIES

We can now use the formalism developed in the previous section to estimate the jet parameters and emission properties in BHBs. In the following we assume a black hole of mass $M = 10\, M_\odot$ and the radius of the jet at $z = 0$ is

$$R_0 = 10r_fR_G = 1.5 \times 10^7 r_f m_1 \, \text{cm}.$$  

If the jet is launched by the accretion disc, the highest and lowest frequencies of variability $f_0$ and $f_1$ must relate to time-scales of the accretion flow. The picture could be similar to that of the model by Lyubarskii (1997) in which density fluctuations generated at a range of disc radii propagate inwards and lead to flicker noise fluctuations of the emission of the inner part of the accretion flow. Similar fluctuations may also lead to a variable velocity of the ejected shells. The detail of how the disc fluctuations are transferred to the jet is out of the scope of this Letter. An interesting possibility is that the rapid episodic ejections could be produced through magnetohydrodynamic mechanisms similar to that leading to coronal mass ejections in the Sun (Yuan et al. 2009). Let $g$ be the ratio of the ejection time-scale $\Delta t = f_0^{-1}/2$ to the Keplerian time-scale of the accretion disc at radius $R_0$. In our numerical estimates we will assume that those time-scales are comparable (i.e. $g \sim 1$):  

$$f_0 \approx 5 \times 10^{-1.3} m_1^{-1} g^{-1} \, \text{Hz}.$$  

Similarly, we associate the lowest frequency of the fluctuations to $2g$ times the dynamical time-scale at a large, possibly outer, radius of the disc $R_d$:

$$f_1 \approx 5 \times 10^{-5} r_5^{-3/2} m_1^{-1} g^{-1} \, \text{Hz}.$$  

We will assume that the fractional rms amplitude of fluctuations of the kinetic power is $\sigma = \gamma_{\text{rms}}/(\gamma - 1) \sim 0.3$, i.e. comparable to that observed in the X-ray variability of BHBs in the hard state. The average travel time of a shell from the ejection point to the first shocks is then

$$z_0 \approx \frac{90}{3} \frac{\gamma + 1}{\sigma_{0.3}} \frac{\gamma \beta}{\sqrt{\gamma^2 + 1}} \frac{g^{3/2} r_5^{1/2} m_1^{1/2}}{\sigma_{0.3}} \, \text{ms},$$  

where $\sigma_{0.3} = \sigma/0.3$ and $\xi = \ln(R_0/R_0)/\ln 10^4$. This time-scale might be related to the delays of comparable amplitude observed between the X-ray emission of the accretion flow and the optical and IR emission from the jet in GX 339–4 (Casella et al. 2010; Gandhi et al. 2010) or XTE J1118+480 (Kanbach et al. 2001; Hynes et al. 2003; Malzac et al. 2003). It corresponds to a lowest distance at which significant emission takes place of

$$z_l \approx 5 \times 10^6 \frac{(\gamma + 1)\beta}{\sqrt{\gamma^2 + 1}} \frac{g^{3/2} r_5^{1/2} m_1^{1/2}}{\sigma_{0.3}} \, \text{cm}.$$  

This is comparable to the distance of $\sim 10^5 R_5$ inferred in Cyg X-1 by both the modelling of SED (Zdziarski et al. 2012) and that of the orbital modulation of the radio emission (Zdziarski 2012). The size of the dissipation region is then

$$z_l \approx 5 \times 10^{15} \frac{(\gamma + 1)\beta}{\sqrt{\gamma^2 + 1}} \frac{g^{3/2} r_5^{1/2} m_1^{1/2}}{\sigma_{0.3}} \, \text{cm},$$  

which is roughly comparable to the extension of the radio jet of Cyg X-1 in the Very Long Baseline Array (VLBA) images of Stirling et al. (2001). These authors also constrain the jet opening angle of
Cyg X-1 to be small $\phi = \phi_1 \pi / 180 \sim 2^\circ$. From this, we can estimate the radius of the jet at the base of the emission region:

$$R_0 \approx 2 \times 10^4 \frac{\sigma_{0,3}^2}{\phi_1 \eta_g \xi} \frac{\sqrt{27}}{\xi} \left( \frac{16 \sqrt{3} \left( \gamma + 1 \right)^{-1} P_{\text{percent}}}{1 + \xi} \frac{r_1}{m_1} \right)^{1/2} \text{cm.}$$  (37)

Here and [O iii] measurements of the optical nebula surrounding Cyg X-1 (Gallo et al. 2005; Russell et al. 2007) indicate that the jet power is of the order of a few percent of the Eddington luminosity $L_E$. This implies a magnetic field at the base of the emission region:

$$B_0 \approx 2 \times 10^4 \frac{\sigma_{0,3}^2}{\phi_1 \eta_g \xi} \left[ \frac{\sqrt{27}}{\xi} \left( \frac{16 \sqrt{3} \left( \gamma + 1 \right)^{-1} P_{\text{percent}}}{1 + \xi} \frac{r_1}{m_1} \right)^{1/2} \right] \left( \frac{D_{\text{jet}}}{2 \text{kpc}} \right) G,$$  (38)

where $P_{\text{percent}} = P_{1}/0.01L_E$. These estimates for $R_0$ and $B_0$ are comparable to the values inferred in Cyg X-1 (Zdziarski et al. 2012), GX 339–4 (Gandhi et al. 2011) and XTE J1550–564 (Chaty et al. 2011). Fixing the parameters of the electron distribution to standard values ($\nu = 2.3$, $\gamma_{max} = 1$ and $\gamma_{min} = 10^3$), we can now evaluate the flux of the flat section of the spectrum:

$$F_{\nu_{0}} \approx 30 \frac{\delta_{0,3}^2 \phi_1^{8/5}\left(1 + \phi_1^{4/5} \right)}{D_{\text{jet}}^{2/5} \phi_1} \left[ \frac{2^{3/2} \nu \left( \gamma + 1 \right)^{1/2}}{1 + \xi} \right] \left( \frac{P_{\text{percent}}}{1 + \xi} \frac{r_1}{m_1} \right)^{(2p+13)/(2p+8)} \text{mJy,}$$  (39)

where $D_{\text{jet}}$ is the distance to the source expressed in kpc. This estimate is consistent with the flux observed in bright hard states (e.g. at $\zeta \approx 2$ kpc, Cyg X-1 has an average radio flux of 15 mJy at 15 GHz). Moreover, we see that for $\nu \alpha 2$ the flux depends on the jet power approximately as $F_{\nu_{0}} \alpha \nu^{1.3}$, as inferred from the observations of the radio–X-ray correlation (Gallo, Fender & Pooley 2003). The turnover frequency is expected to reach the in-mid-IR, in agreement with the observations of Cyg X-1 (Rahoui et al. 2011) or GX 339–4 (Gandhi et al. 2011):

$$n_1 \approx 1.8 \times 10^{13} n_{1}^{-3/2} \text{Hz},$$  (40)

where

$$n_1 = \frac{\delta_{0,3}^2 \phi_1^{8/5} \left(1 + \phi_1^{4/5} \right)}{\eta_g \phi_1^{4/5} \left(1 + \phi_1^{4/5} \right)} \left( \frac{2 P_{\text{percent}}}{1 + \xi} \right) \left( \frac{r_1}{m_1} \right)^{(2p+13)/(2p+8)} \text{mJy,}$$  (41)

Finally, the model predicts that the emission should decrease significantly at frequencies below:

$$n_1 \approx 40 n_{1}^{-3/2} \text{MHz},$$  (42)

and this is something that can be investigated in the near future with LOR Frequency ARray (LOFAR). Note that in Fig. 1, $v_1$ occurs at much higher frequencies (a few GHz). Indeed, because simulating very long time-scale fluctuations is time consuming, $f_1$ was set to $1.6 \times 10^{-3}$ Hz in Fig. 1, rather than $\sim 5 \times 10^{-5}$ Hz as given by equation (33).

We conclude that internal shocks driven by flicker noise fluctuations can produce not only the flat SED of compact jets in BHBs, but also other properties such as the flux amplitude or the location of the break frequency. The model also predicts strong multiwavelength variability that will be the focus of future works.
