Abstract.—Standard models of molecular evolution cannot estimate absolute speciation times alone, and require external calibrations to do so, such as fossils. Because fossil calibration methods rely on the incomplete fossil record, a great number of nodes in the tree of life cannot be dated precisely. However, many major paleo-geographical events are dated, and since biogeographical processes depend on paleo-geographical conditions, biogeographic dating may be used as an alternative or complementary method to fossil dating. I demonstrate how a time-stratified biogeographic stochastic process may be used to estimate absolute divergence times by conditioning on dated paleo-geographical events. Informed by the current paleo-geographical literature, I construct an empirical dispersal graph using 25 areas and 26 epochs for the past 540 Ma of Earth’s history. Simulations indicate biogeographic dating performs well so long as paleo-geography imposes constraint on biogeographic character evolution. To gauge whether biogeographic dating may be of practical use, I analyzed the well-studied turtle clade (Testudines) to assess how well biogeographic dating fares when compared to fossil-calibrated dating estimates reported in the literature. Fossil-free biogeographic dating estimated the age of the most recent common ancestor of extant turtles to be from the Late Triassic, which is consistent with fossil-based estimates. Dating precision improves further when including a root node fossil calibration. The described model, paleo-geographical dispersal graph, and analysis scripts are available for use with RevBayes. [biogeography, phylogenetics, paleo-geography, tree-dating, T estudines, Bayesian.]

Time is a simple and fundamental axis of evolution. Knowing the order and timing of evolutionary events grants us insight into how vying evolutionary processes interact. With a perfectly accurate catalog of geologically dated speciation times, many macro-evolutionary questions would yield to simple interrogation, such as whether one clade exploded with diversity before or after a niche-analogous clade went extinct, or whether some number of contemporaneous biota were eradicated simultaneously by the same mass extinction event. Only rarely does the fossil record give audience to the exact history of evolutionary events; it is infamously irregular across time, space, and species, so biologists generally resort to inference to estimate when, where, and what happened to fill those gaps. That said, we have not yet found a perfect character or model to infer dates for divergence times, so advances in dating strategies are urgently needed. A brief survey of the field reveals why.

The molecular clock hypothesis of Zuckerkandl and Pauling (1962) states that if substitutions arise (i.e., alleles fix) at a constant rate, the expected number of substitutions is the product of the substitution rate and the time the substitution process has been operating. With data from extant taxa, we only observe the outcome of the evolutionary process for an unknown rate and an unknown amount of time. In this case, rate and time are not separately identifiable, so they are estimated as their product, a compound parameter called length. If all species evolved under a single rate (a strict clock), a phylogeny with branches measured in lengths would give relative divergence times, that is, proportional to absolute divergence times. The same is true when substitution rates vary across lineages (Wolfe et al. 1987; Martin and Palumbi 1993) and relaxed clock models are applied (Thorne et al. 1998; Drummond et al. 2006): only relative times may be estimated. Extrinsic information, for example, a dated calibration density, is needed to establish an absolute timescale, and typically takes form as a fossil occurrence or paleo-geographical event.

Fossils may be used in several ways to calibrate divergence times. The simplest method is the fossil node calibration, whereby the fossil is associated with a clade to constrain its time of origin (Ho and Phillips 2009; Parham et al. 2012). Node calibrations are empirical priors, not data-dependent stochastic processes, so they depend on experts’ abilities to quantify the distribution of plausible ages for the given node. That is, node calibrations do not arise from a generative evolutionary process, so the posterior timescale is entirely determined by how the prior is specified. Rather than using prior node calibrations, fossil tip-dating (Pyron 2011; Ronquist et al. 2012) treats fossil occurrences as terminal taxa with morphological characters as part of any standard phylogenetic analysis. The tree prior and model of morphological evolution are jointly applied to date speciation times from the fossils’ ages and morphological data. Introducing a generative process of fossilization, Heath et al. (2014) developed the fossilized birth–death process, by which lineages speciate, go extinct, or produce fossil observations. Using fossil tip-dating with the fossilized birth–death process, Zhang et al. (2015) and Gavryushkina et al. (2015) demonstrated multiple calibration techniques may be used in tandem in a theoretically consistent framework (i.e. without introducing model violation).

Of course, fossil calibrations require fossils, but many clades leave few to no known fossils due to taphonomic processes, which filter out species with soft or fragile tissues, or with tissues that were buried in substrates...
that were too humid, too arid, or too rocky; or due to sampling biases, such as geographical or political biases imbalancing collection efforts (Behrensmeyer et al. 2000; Kidwell and Holland 2002). Although these biases do not prohibitively obscure the record for widespread species with robust mineralized skeletons—as is the case for many marine invertebrate and large vertebrate groups—fossil-free calibration methods are desperately needed to date the remaining majority of nodes in the tree of life.

In this direction, analogous to fossil node-dating, node dates may be calibrated using paleobiogeographic scenarios (Heads 2005; Renner 2005). An ornithologist, for example, might reasonably argue that a bird known as endemic to a young island may have speciated only after the island was created, thus providing a maximum age of origin. However, using this scenario as a calibration excludes the possibility of alternative historical biogeographic explanations, for example, the bird might have speciated off-island before the island surfaced and migrated there afterward; see Heads (2005, 2011), Kodandaramaiah (2011), and Ho et al. (2015) for discussion on the uses and pitfalls of biogeographic node calibrations. Biogeographic node calibrations, like fossil node calibrations, fundamentally rely on some prior distribution of divergence times. This complicates model comparison since prior-encoded beliefs vary from expert to expert. Worsening matters, the time and context of biogeographic events are never directly observed, so asserting that a particular dispersal event into an island system resulted in a speciation event to calibrate a node fails to account for the uncertainty that the assumed evolutionary scenario took place at all. When estimating ancestral states, phylogenies dated by biogeographic node calibrations should be avoided, for fear of producing falsely confident results by “double counting” the data: once when justifying the node calibrations and again when performing the biogeographic inference. Ideally, to avoid these problems, all possible biogeographic and diversification scenarios would be considered jointly, with each scenario given credence in proportion to its probability.

Inspired by advents in fossil dating models (Pyron 2011; Ronquist et al. 2012; Heath et al. 2014), which have matured from phenomenological toward mechanistic approaches (Rodrique and Philippe 2010), I present an explicitly data-dependent and process-based biogeographic method for divergence time dating to formalize the intuition underlying biogeographic node calibrations. Analogous to fossil tip-dating, the goal is to allow the observed biogeographic states at the “tips” of the tree to induce a posterior distribution of dated speciation times by way of an evolutionary process. By modeling dispersal rates between areas as subject to time-calibrated paleogeographical information, such as the merging and splitting of continental adjacencies due to tectonic drift, particular dispersal events between area-pairs are expected to occur with higher probability during certain geological time intervals than during others. For example, the dispersal rate between South America and Africa was likely to be higher when they were joined as West Gondwana (ca. 120 Ma) than when separated as they are today. If the absolute timing of dispersal events on a phylogeny matters, then so must the absolute timing of divergence events. Unlike fossil tip-dating, biogeographic dating should, in principle, be able to date speciation times only using extant taxa.

To illustrate how this is possible, I construct a toy biogeographic example to demonstrate when paleogeography may date divergence times, then follow with a more formal description of the model. By performing joint inference with molecular and biogeographic data, I demonstrate the effectiveness of biogeographic dating by applying it to simulated and empirical scenarios, showing rate and time are identifiable. While researchers have accounted for phylogenetic uncertainty in biogeographic analyses (Nylander et al. 2008; Lemey et al. 2009; Beaulieu et al. 2013), I am unaware of work demonstrating how paleoecogeographic calibrations may be leveraged to date divergence times via a biogeographic process. For the empirical analysis, I date the divergence times for Testudines using biogeographic dating, first without any fossils, then using a fossil root node calibration. Finally, I discuss the strengths and weaknesses of the method, and how it may be improved in future work.

**Model**

**The Anatomy of Biogeographic Dating**

Briefly, I will introduce an example of how time-calibrated paleoecogeographical events may impart information through a biogeographic process to date speciation times, then later develop the details underlying the strategy, which I refer to as biogeographic dating. Throughout the article, I assume a rooted phylogeny with known topology but with unknown divergence times that I wish to estimate. Time is measured in geological units and as time until present, with $t=0$ being the present, $t<0$ being the past, and age being the negative amount of time until present. To keep the model of biogeographic evolution simple, the observed taxon occurrence matrix is assumed to be generated by a discrete-valued dispersal process where each taxon is present in only a single area at a time (Sanmartín et al. 2008). For example, taxon $T1$ might be coded to be found in area $A$ or area $B$, but not both simultaneously. Although basic, this model is sufficient to make use of paleoecogeographical information, suggesting more realistic models will fare better.

Consider two areas, $A$ and $B$, that drift into and out of contact over time. When in contact, dispersal is possible; when not, impossible. The dispersal rate between $A$ and $B$ equals one when the dispersal route exists, and equals zero when it does not. When $A$ and $B$ have a dispersal rate of zero, because the two areas are not connected by alternate dispersal routes, however circuitous, the probability of transitioning from area $A$ to area $B$ equals zero no matter how much time elapses. Under this construction, certain types of dispersal events are more
likely to occur during certain absolute (not relative) time intervals, which potentially influences probabilities of divergence times in absolute units.

In practice, biogeographic dating requires three sources of data: molecular data to accurately estimate the relative branch lengths and (if desired) topology of a rooted species tree, biogeographic data to inform the biogeographic process that in turn informs the branch lengths in absolute time, and an empirical paleogeographic model that alters the rates of biogeographic change over time. As later described in the “Analysis” section, these data are jointly analyzed in a Bayesian framework using RevBayes (Höhna et al. 2014), but the general concept is not wed to a particular inference methodology.

Below, I give examples of when a key divergence event is likely to precede a split event (Figs. 1a,b) or to follow a merge event (Figs. 1c,d). To simplify matters without compromising the general logic of the method, I assume only a single change occurs on a particular branch given the topology and tip states. In this sense, the toy examples resemble parsimony reconstructions, except they depend critically on branch length information.

In the first scenario (Figs. 1a,b), sister taxa T2 and T3 are found in areas A and B, respectively. The divergence time, \( t_s \), is a random variable to be inferred. At time \( t \), the dispersal route (A, B) is destroyed, inducing the transition probability between areas A and B to equal zero between times \( t \) and 0. Since T2 and T3 are found in different areas, at least one dispersal event must have occurred during an interval of non-zero dispersal probability. Then, the divergence event that gave rise to T2 and T3 must have also predated \( t \), with at least one dispersal event occurring before the split event (Fig. 1a). If T2 and T3 diverge after \( t \), a dispersal event from A to B is necessary to explain the observations (Fig. 1b), but the model disfavors that divergence time because the required transition has probability zero. In this case, the creation of a dispersal barrier informs the latest possible divergence time, a threshold after which divergence between T2 and T3 is distinctly less probable if not impossible. It is also worth considering that a more complex process modeling vicariant speciation would provide tighter thresholds centered on \( t \) (see “Discussion” section).

In the second scenario (Figs. 1c,d), the removal of a dispersal barrier is capable of creating a maximum divergence time threshold, pushing divergence times toward the present. To demonstrate this, say the ingroup sister taxa T3 and T4 both inhabit area B and the
A time-heterogeneous continuous-time Markov chain (CTMC) will be used to model the formal behavior outlined in the toy example above. The CTMC is attractive as an evolutionary model because its transition probabilities may be efficiently computed for any given instantaneous rate matrix, $Q$, and the amount of time a lineage has been evolving, $t$. Under the CTMC, the transition probability matrix, $P(t)$, reports the probability that a lineage beginning in one character state ends in any particular state after time $t$ by considering the infinite number of possible evolutionary histories consistent with the start and end states. Structuring the dispersal rates will, therefore, leave its impression upon the resulting dispersal probabilities.

Here, the paleogeographical features that determine the dispersal process rates are assumed to follow a piecewise constant model, sometimes called a stratified (Ree et al. 2005; Ree and Smith 2008) or epoch model (Bielejec et al. 2014), where $K$ breakpoints are dated in geological time to create $K$ time intervals. The addition and removal of dispersal routes demarcate time intervals, or epochs, each corresponding to some epoch index, $k \in \{1, \ldots, K\}$. Note, these epochs are time intervals defined by the model and do not necessarily coincide with geological epochs. These breakpoint times populate the vector, $\tau=(\tau_0=\infty, \tau_1, \tau_2, \ldots, \tau_{K-1}, \tau_K=0)$, with the oldest interval spanning deep into the past, and the youngest interval spanning to the present.

For a time-homogeneous CTMC, the transition probability matrix is typically written as $P(\tau)$, which is computed for some branch length, $t$, using the parameters $Q$, the rate matrix, and $\mu$, the clock rate. For a piecewise constant CTMC, the value of the rate matrix, $Q(k)$, changes as a function of the underlying time interval. While a lineage exists during the $k$-th time interval, its biogeographic characters evolve according to that interval’s rate matrix, $Q(k)$, whose rates are informed by paleogeographical features present during the epoch spanning $[\tau_{k-1}, \tau_k]$. As an example of a paleographically informed matrix’s structure, take $G(k)$ to be an adjacency matrix indicating 1 when dispersal may occur between two areas and 0 otherwise, during time interval $k$. This adjacency matrix is equivalent to an undirected graph where areas are vertices and edges are dispersal routes. Full empirical examples of $G=G(1), G(2), \ldots, G(K)$ describing Earth’s paleocontinental adjacencies are given in detail later (section “Adjacent-Area Terrestrial Dispersal Graph”). With the paleogeographical vector $G$, I define the transition rates of $Q(k)$ as equal to $G(k)$, with the rate matrix of each epoch rescaled to have an average rate of one. Similar rate matrices are constructed for all $K$ time intervals that contain possible supported root ages for the phylogeny. Supplementary Figure S1 (available on Dryad at http://dx.doi.org/10.5061/dryad.dq666) provides an example of two epochs with differing transition probability matrices.

The transition probability matrix for the piecewise constant process, $P(s,t)$, is the matrix product of the constituent epochs’ time-homogeneous transition probability matrices, and takes a value determined by the absolute time and order of paleogeographical events contained between the start time, $s$, and end time, $t$. Under this construction, certain types of dispersal events are more likely to occur during certain absolute (not relative) time intervals, which potentially influences probabilities of divergence times in absolute units.

For a piecewise constant CTMC, the process’s transition probability matrix is the product of transition probability matrices spanning $m$ breakpoints. To simplify notation, let $v$ be the vector marking important times of events, beginning with the start time of the branch, $s$, followed by the $m$ breakpoints satisfying $s<\tau_1<\tau_2<\ldots<\tau_m<\tau_t$, ending with the end time of the branch, $t$, such that $v=(s, \tau_1, \tau_2, \ldots, \tau_m, t)$, and let $u(t)$ be a “look-up” function that gives the index $k$ that satisfies $\tau_{k-1}<t\leq\tau_k$. The transition probability matrix over the intervals in $v$ according to the piecewise constant CTMC given by the vectors $\tau$ and $Q$ is:

$$P_v(s, t, \mu, \tau, Q) = \prod_{i=1}^{m+1} \mu(s, t, \mu, \tau, Q, i)$$

The pruning algorithm (Felsenstein 1981) is agnostic as to how the transition probabilities are computed per branch, so introducing the piecewise constant CTMC does not prohibit the efficient computation of phylogenetic model likelihoods; Bielejec et al. (2014) provides an excellent review of piecewise constant CTMCs as applied to phylogenetics.

For a time-homogeneous model where $\tau=(-\infty, 0)$, multiplying the rate and dividing the branch length by the same factor results in an identical transition probability matrix. In practice, the time-homogeneous model provides no information for the values of the clock rate and the branch lengths in the tree, since all branch rates could likewise be multiplied by some constant while branch lengths were divided by the same constant, that is, $P_v(s, t, 1, \tau, Q) = P_v(s, t, 1, \mu, \tau, Q)$. Similarly, assuming time homogeneity, only the elapsed amount of time—but not the absolute times the process starts
and ends running—affects the transition probabilities, that is, \( P_v((s,t),\mu,t;t,Q) = P_v((s+c,t+c),\mu,t;Q) \). In contrast, the times \( s \) and \( t \) are identifiable from \( \mu \) so long as \( P_v((s,\mu,\mu',t,Q) \neq P_v((s',\mu',\mu',t,Q) \) for the supported values of \( v,\mu,\mu' \), and \( \mu \) under time-heterogeneous CTMCs. Expanding from a treeless branch to the set of branches embedded in a time tree, the node ages would be identifiable so long as no two sets of node age values share identical phylogenetic model likelihoods. Barring pathological examples, the possibility that likelihood-equivalent parameters exist will generally decrease as the structural complexity of the time-heterogeneous model increases. Proving the particular conditions for which node ages are (or are not) identifiable under a time-heterogeneous model is a challenging and open question, but may be explored numerically through simulations.

The paleogeographically structured biogeographic CTMC described in this section is one example of a rate-time identifiable time-heterogeneous stochastic process. More broadly, any time-heterogeneous evolutionary process with transition probabilities influenced by dated historical observations should be capable of inducing a time-calibrated distribution of speciation times. In this framework, the quality of the estimate would largely depend on whether those influences are modeled in a realistic, justified, and principled manner.

### Paleography, Dispersal Graphs, and Markov Chains

Fundamentally, biogeographic dating depends on how rapidly particular types of biogeographic events occur, and how the rates of biogeographic evolution change over time. The dispersal scenarios in Figure 1 depend on the notion of reachability, which I develop to build intuition for how the method works. For simplicity, I will assume the dispersal rates between pairs of areas are symmetric. One area is reachable by another area so long as they are connected by some series of dispersal routes of any length, called a path. A path may be thought of as any potential sequence of evolutionary events that allows a lineage to disperse from one area to another, including the use of dispersal events through intermediate areas. Under a CTMC, for any positive amount of time, the transition probability between areas is positive if the areas share at least one path, and zero if they do not. This property potentially gives rise to distinct communicating classes. Each communicating class contains all areas that are mutually reachable, and hence share positive transition probabilities. Conversely, the transition probabilities between areas belonging to different communicating classes equal zero, as they are unreachable. Because the area adjacencies change per epoch under a paleogeographical model, so do the corresponding transition probabilities and communicating classes. Taking terrestrial biogeography as an example, areas exclusive to Gondwana or Laurasia may each reasonably form communicating classes upon the break-up of Pangaea (Fig. 2), meaning lineages are free to disperse between areas within these paleocontinents, but not to and from areas on other paleocontinents. For example, the set of communicating classes is \( S = \{[\text{Afr}], [\text{As}], [\text{Ind}]\} \) at \( t = -100 \), that is, there are \( |S| = 3 \) communicating classes because no areas share edges (Fig. 2e), while at \( t = -10 \) there is \( |S| = 1 \) communicating class since a path exists between all three pairs of areas (Fig. 2e).

In one extreme case, dispersals between mutually unreachable areas do not occur even after infinite time, and hence have zero probability. At the other extreme, when dispersal may occur between any pair of areas with equal probability over all time intervals, then paleoecography does not favor nor disfavor dispersal events (nor divergence events, implicitly) to occur during particular time intervals. In intermediate cases, where dispersal probabilities between areas vary across time intervals, the dispersal process informs when and what dispersal (and divergence) events occur. For instance, the transition probability of going from area \( i \) to \( j \) decreases as the average path length between \( i \) and \( j \) increases. During some time intervals, the average path length between two areas might be short, thus dispersal events occur more freely than when the average path is long. Comparing Figure 2a and e, the minimum number of events required to disperse from India to Africa is smaller during the Triassic (e.g., at \( t = -250 \)) than during the present (\( t = 0 \)), and thus would have a relatively higher probability given the process operating for the same amount of time today (e.g., for a branch with the same length). Interestingly, even lineages with no biogeographic variation impart some information for when a period of biogeographic stasis might begin. It will be most probable for a lineage to remain in a given area during epochs where the area is not connected to any dispersal routes. This particular signal of stasis is difficult, if not impossible, to account for under parsimony and node-based calibration methods.

Specifying communicating classes is partly difficult because we do not know the ease of dispersal between areas for most species throughout space and time. Biologically, encoding zero-valued dispersal rates directly into the model should be avoided given the apparent prevalence of long-distance dispersal, sweepstakes dispersal, etc. across dispersal barriers (Carlquist 1966). Mathematically, zero-valued rates may imply that dispersal events between certain areas are not merely improbable but utterly impossible, creating troughs of zero likelihood in the likelihood surface for certain dated-phylogeny-character patterns (Buerki et al. 2011). In a biogeographic dating framework, this might unintentionally eliminate large numbers of speciation scenarios from the space of possible hypotheses, resulting in distorted estimates. To avoid these problems, I take the dispersal graph as the weighted average of three distinct dispersal graphs assuming short-, medium-, or long-distance dispersal modes, each with their own set of communicating classes (see section “Adjacent-Area Terrestrial Dispersal Graph”).
FIGURE 2. Biogeographic communicating classes. Dispersal routes shared by Africa (Afr), Asia (As), and India (Ind) are depicted for five consecutive epochs (a-e) over the past 300 Ma. Time intervals for each epoch are given by $t$. Dispersal path lengths between areas $i$ and $j$ are given by $d_{i,j}$, with NA meaning there is no route between areas ($i$ and $j$) are mutually unreachable. Communicating classes per interval are given by $S$ and by the shared coloring of areas (vertices), with $|S|$ being the number of communicating classes.

The concepts of adjacency, reachability, and communicating classes are not necessary to structure the rate matrix such that biogeographic events inform divergence times, though their simplicity is attractive. One could yield similar effects by parameterizing dispersal rates as functions of more complex area features, such as geographical distance between areas (Webb and Ree 2012; Landis et al. 2013) or the size of areas (Tagliacollo et al. 2015). In this study, the concepts introduced in this section serve the practical purpose of summarizing perhaps the most salient feature of global paleogeography—that continents were not always configured as they are today—but also illuminate how time-heterogeneous dispersal rates produce transition probabilities that depend on geological time, which in turn inform the dates of speciation times.

**Adjacent-Area Terrestrial Dispersal Graph**

I identified $K=26$ times and $N=25$ areas to capture the general features of continental drift and its effects on terrestrial dispersal (Fig. 3; Supplemental Figure S8 available on Dryad). All adjacencies were constructed visually, referencing Blakey (2006) and GPlates (Boyden et al. 2011), then corroborated using various paleogeographical sources (Supplementary Table S2 available on Dryad). The paleogeographical state per time interval is summarized as an undirected graph, where areas are vertices and dispersal routes are edges.

To proceed, I treat the paleogeographical states over time as a vector of adjacency matrices, where $G_k(i,j)=1$ if areas $i$ and $j$ share a dispersal edge at time interval $k$, and $G_k(i,j)=0$ otherwise. A subscript $\bullet$ is used to distinguish adjacency matrices generated under alternative area adjacency criteria. Temporarily, I suppress the time index, $k$, for the rate matrix $Q$, since all time intervals’ rate matrices are constructed in a similar manner. To mitigate the effects of model misspecification, $Q$ is determined by a weighted average of three geographical adjacency matrices

$$ G = b_sG_s + b_mG_m + b_lG_l $$

where $s$, $m$, and $l$ correspond to short-, medium-, and long-distance dispersal modes. The parameters $b_s$, $b_m$, and $b_l$ sum to 1 and are to be estimated, thus weighing
FIGURE 3. Dispersal graph for Epoch 14, 110–100Ma: India and Madagascar separate from Australia and Antarctica. A GPlates (Gurnis et al. 2012) screenshot of Epoch 14 of 26 is displayed. Areas are marked by black vertices. Black edges indicate both short- and medium-distance dispersal routes. Gray edges indicate exclusively medium-distance dispersal routes. Long-distance dispersal routes are not shown, but are implied to exist between all area-pairs. The short-, medium-, and long-distance dispersal graphs have 8, 1, and 1 communicating classes, respectively. Only India may reach Madagascar by short-distance dispersal, and vice versa, forming one of the eight short-distance communicating classes. Both areas maintain medium-distance dispersal routes with various Gondwanan continents during this epoch. The expansion of the Tethys Sea impedes dispersal into and out of Europe. Section “Paleogeography, Dispersal Graphs, and Markov Chains” explains how communicating classes are determined.

the importance of each dispersal mode according to the data. Short-, medium-, and long-distance dispersal processes encode strong, weak, and no geographical constraint, respectively. As distance-constrained mode weights $b_s$ and $b_m$ increase, the dispersal process grows more prone to remaining within a particular communicating class (Supplementary Fig. S2 available on Dryad). The vector of short-distance dispersal graphs, $G_s = (G_s(1), G_s(2), \ldots, G_s(K))$, marks adjacencies for pairs of areas that allow terrestrial dispersal without traveling over bodies of water (Supplementary Figs. S2a,b available on Dryad). Medium-distance dispersal graphs, $G_m$, include all adjacencies in $G_s$ in addition to adjacencies for areas separated by lesser bodies of water, such as throughout the Malay Archipelago, while excluding transoceanic adjacencies, such as between South America and Africa (Supplementary Figs. S2c,d available on Dryad). Finally, long-distance dispersal graphs, $G_l$, allow dispersal events to occur between any pair of areas, regardless of potential barrier (Supplementary Figs. S2e,f available on Dryad).

To average over the three dispersal modes, $b_s$, $b_m$, and $b_l$ are constrained to sum to 1, causing all elements in $G$ to take values from 0 to 1 (Equation 1). Importantly, adjacencies specified by $G_s$ always equal 1, since those adjacencies are also found in $G_m$ and $G_l$. This means $Q$ is a Jukes–Cantor rate matrix only when $b_l = 1$, but becomes increasingly paleogeographically structured as $b_l \to 0$. Non-diagonal elements of $Q$ equal those of $G$, but are rescaled such that the average number of transitions per unit time is one, while diagonal elements of $Q$ equal the negative sum of the remaining row elements. To compute transition probabilities, $Q$ is later rescaled by a biogeographic clock rate, $\mu$, prior to matrix exponentiation. The effects of the weights $b_s$, $b_m$, and $b_l$ on dispersal rates between areas are shown in Figure 4.

By the argument that continental break-up (i.e., the creation of new communicating classes; Figs. 1a,b) introduces a lower threshold on the minimum age of divergence, and that continental joining (i.e., unifying existing communicating classes; Figs. 1c,d) introduces an upper threshold on the maximum age of divergence, then the paleogeographical model I constructed has the greatest potential to provide both upper and lower thresholds (soft bounds) on divergence times when the number of communicating classes is large; then small, then large again. This coincides with the formation of Pangaea, dropping from 8 to 3 communicating classes at 280 Ma, followed by the fragmentation of Pangaea, increasing from 3 to 11 communicating classes between 170 Ma and 100 Ma (Fig. 5). It is important to consider this bottleneck in the number of communicating classes will be informative of root age only for fortuitous combinations of species range and species phylogeny. Just as some clades lack a fossil record, others are bound...
Two further assumptions were made to simplify the analyses. First, although divergence times were free to vary, the tree topology was assumed to be known. Second, molecular and biogeographic characters evolve by strict global clocks. In principle, inferring the topology or using relaxed clock models should increase the variance in posterior divergence time estimates, but not greatly distort the performance of –G relative to +G.

Phylogenies with \( M = 50 \) extant taxa were simulated using a birth–death process with birth rate, \( \lambda = 0.25 \), and death rate, \( \mu = 0.15 \), then rescaled so the root age equaled 250 Ma. Each data set contained 500 nucleotides and 1 biogeographic character. Biogeographic characters were simulated under +G, where \( G \) is defined as piecewise constant over 25 areas and 26 time intervals in the manner described in section “Adjacent-Area Terrestrial Dispersal Graph”.

In total, I simulated 100 data sets under the parameter values given in Table 1, where these values were chosen to reflect possible empirical estimates. Each data set was analyzed under each of two models, then analyzed a second time to verify convergence (Gelman and Rubin 1992; Plummer et al. 2006). When summarizing posterior results, posterior mean-of-median and 95% highest posterior density (HPD95%) values were presented.

As expected, the results show the –G model extracts no information regarding the root age, so its posterior distribution equals its prior distribution, mean-of-median \( = 499 \) (Fig. 6a). In contrast, the +G model infers the mean-of-median root age 243 with a HPD95% interval width of 436, improving accuracy and precision in general.

Estimated divergence time accuracy was assessed with the statistic

\[
d = \sum_{i} \frac{d_i^{(true)} - d_i^{(true)}}{d_i^{(true)}}
\]

where \( a \) is a posterior sample of the node age vector and \( a^{(true)} \) is the true node age vector known through simulation. When \( a \) perfectly estimates \( a^{(true)} \) for all node ages, \( d = 0 \). When estimated node ages are too young (on average), \( d < 0 \) and when too old, \( d > 0 \). Inference under +G infers an mean \( d = 0.19 \) with a HPD95% interval width of \( \approx 1.26 \), while –G performs substantially worse with \( d = 0.92 \) and width \( \approx 2.75 \) (Fig. 6b). Posterior estimates generally favored short- over medium- and long-distance dispersal as was assumed under simulation (Fig. 6c).

**Dispersion between As and Ind occurs over a long-distance dispersal edge with weight \( w = 0.3 \).**

**Analysis**

All posterior densities were estimated using Markov chain Monte Carlo (MCMC) as implemented in RevBayes available at http://revbayes.com (Hohen et al. 2014). Data and analysis scripts are available both on Dryad (http://dx.doi.org/10.5061/dryad.dq666) and on GitHub (http://github.com/mlandis/biogeodating). Analyses were performed on the XSEDE supercomputing cluster (Towns et al. 2014).

**Simulation**

Through simulation I tested whether biogeographic dating identifies rate from time. The simulation analyses were designed only to verify that the method was adequately well-behaved to merit further study. To proceed, I designed the analysis so divergence times are adequately well-behaved to merit further study. To further subdue effects from the prior on posterior parameter estimates, the tree prior assigns equal probability to all node age distributions. No node calibrations were used. Each data set was analyzed with (+G) and without (–G) the paleogeographic-dependent dispersal process.
found predominantly in the Northern hemisphere. Their modern distribution shadows their biogeographic history, where *Testudines* is thought to be Gondwanan in origin with the ancestor to cryptodires dispersing into Laurasia during the Jurassic (Crawford et al. 2015).

Since turtles are among the best preserved vertebrates in the fossil record, their phylogeny and divergence times have been profitably analyzed and reanalyzed by various researchers (Hugall et al. 2007; Joyce 2007; Danilov and Parham 2008; Alfaro et al. 2009; Dornburg et al. 2011; Joyce et al. 2013; Sterli et al. 2013; Warnock et al. 2015). This makes them ideal to assess the efficacy of biogeographic dating, which makes no use of their replete fossil record: if both biogeography-based and fossil-based methods generate similar results, they co-validate each others’ correctness (assuming they are not both biased in the same manner).

To proceed, I assembled a moderately sized dataset. First, I aligned cytochrome B sequences for 185 turtle species (155 cryptodires, 30 pleurodires) using MUSCLE 3.8.31 (Edgar 2004) under the default settings. Assuming the 25-area model presented in section “Adjacent-Area Terrestrial Dispersal Graph”, I consulted GBIF (gbif.org) and IUCN Red List (iucnredlist.org) to record the area(s) in which each species was found. Species occupying multiple areas were assigned ambiguous tip states for those areas. Missing data entries were assigned to the six sea turtle species used in this study to effectively eliminate their influence on the (terrestrial) biogeographic process. To simplify the analysis, I...

**Notes:** Model parameter names and prior distributions are described in the manuscript body. All empirical priors were identical to simulated priors unless otherwise stated. Priors used for the empirical analyses but not simulated analyses are left blank. Determined means the parameter value was determined by other model parameters.

---

**Figure 6.** Posterior estimates for simulated data. a) Posterior estimates of root age. The true root age for all simulations is 250 Ma (dotted vertical line). b) Posterior estimates of relative node age error (Equation 2). The true error term equals zero. Both a and b) paleogeographically non-informed (-G) analyses are on the top half, and paleogeographically informed (+G) analyses are on the bottom. Each square marks the posterior mean root age estimate with the HPD95% credible interval. Estimates whose credible interval did not contain the true value are darkened for visibility. c) Posterior estimates of dispersal mode proportions for the +G simulations projected onto the unit 2-simplex. The filled square (near "short") gives the true value, and the empty circles give posterior medians.
assumed the species tree topology was fixed according to Guillen et al. (2012), which was chosen for its high species coverage. All speciation times were treated as random variables to be estimated. The tree topology and biogeographic states are shown in Supplementary Fig. S4 available on Dryad.

Like the simulation study, my aim is to show that the paleogeographically aware +G model identifies the root age in units of absolute time. To reiterate, the posterior root age should be identical to the prior root age when the model cannot inform the root age. If the prior and posterior differ, then the data under the model are informative. The root age was constrained to Uniform(0,540), forbidding the existence of Precambrian turtles. To improve biological realism, I further relaxed Uniform(0,540), following Joyce et al. (2013) and assumed Uniform(155.7, 251.4) as a root node age calibration. Line types indicate priors on dispersal mode (solid: prior flat, dashed: short-biased, dotted: paleogeography ignored).

Biogeographic dating infers a posterior median root age of 219.0 with HPD95% credible interval of (134.9, 358.3) (Fig. 7). This is consistent with current root age estimates informed from the fossil record (Fig. 8). The posterior median of dispersal mode is Dirichlet(1,1,1) and does not capture the intuition that short-distance dispersal should be far more common than long-distance dispersal. I encoded this intuition in the dispersal mode prior, setting the distribution to Dirichlet(100, 10, 1), which induces an expected proportion of 100:10:1 short-, medium-, and long-distance dispersal events. After reanalyzing the data with the short-biased dispersal prior, the posterior median and HPD95% credible interval for the root age were estimated to be, respectively, 208.3 and (99.5, 290.2) (Fig. 7). Biogeographic dating is compatible with fossil dating methods, so I repeated the analysis for both flat and informative prior dispersal modes while substituting the Uniform(0, 540) prior on root age calibration for Uniform(155.7, 251.4), following Joyce et al. (2013).

Although additional fossil node calibrations were available, they were not used to avoid inducing a nonuniform prior density for the root age (Warnock et al. 2015). When taking biogeography into account with the root age calibration, the model more strongly disfavors post-Pangaean origins for the clade than when biogeography is ignored, but the effect is mild (Fig. 7). Posterior distributions of root age were relatively insensitive to the flat and short-biased dispersal mode priors, with posterior median and credible intervals of 203.4 (163.9, 251.2) and 205.8 (165.0, 251.2), respectively. Because of the design of the model, it is unsurprising that the root node calibration prior effectively truncates the full, uncalibrated posterior density.

All posterior root state estimates favored South America for the paleogeographically informed analyses (Fig. 9a). Although this is in accord with the root node calibration adopted from Joyce et al. (2013)—Caribbean oxysternids, sampled from Cuba, and the oldest described crown group testudine—the fossil is described as a marine turtle, so the accordance may simply be coincidence, especially in light of the complicated history of the Caribbean Plate. In contrast, the paleogeographically naive models support a Southeast Asian origin of Testudines, where, incidentally,
Southeast Asia is the most frequently inhabited area among the 185 testudines. For the analysis with a flat dispersal mode prior and no root age calibration, all root states with high posterior probability appear to concur upon the posterior root age density (Fig. 9b), that is, regardless of conditioning on the northern area of South America or either of the two southern areas in North America as a root state, the posterior root age density is roughly equal. Similarly, poorly supported areas of origin contribute almost nothing to the root age density. The joint-marginal density shared by the root age and root state variables bears a strong signature of a unimodality, for example, young and old origination times do not support conflicting areas of origin. Ancestral biogeographic state estimates for the entire clade are available as Supplementary Figs. S5–S7.

**DISCUSSION**

A major obstacle preventing the probabilistic union of paleogeographical knowledge, biogeographic inference, and divergence time estimation has been methodological, which I have attempted to redress in this article. The intuition justifying prior-based fossil calibrations (Parham et al. 2012), that is, that fossil occurrences should somehow inform divergence times, has recently been formalized into several models (Pyron 2011; Ronquist et al. 2012; Heath et al. 2014). Here, I present an analogous treatment for prior-based biogeographic calibrations, that is, that biogeographic patterns of modern species echo time-calibrated paleobiogeographic events, by describing how epoch models (Ree et al. 2005; Ree and Smith 2008; Bielejec 2011; Danilov and Parham 2008; DeMoor et al. 2010; Joyce et al. 2013; Sterli et al. 2013; Alfaro et al. 2009; Dornburg et al. 2011; Hugall et al. 2007; Warnock et al. 2015; Joyce et al. 2013) report many estimates while exploring prior sensitivity, but only uniform prior results are shown here.
et al. 2014) are informative of absolute divergence times. Briefly, I accomplished this using a simple time-heterogeneous dispersal process (Sanmartín et al. 2008), where dispersal rates are piecewise constant, and determined by a graph-based palaeogeographical model (section "Adjacent-Area Terrestrial Dispersal Graph").

The palaeogeographical model itself was constructed by translating various published palaeogeographical reconstructions (Supplementary Table S2 available on Dryad) into a time-calibrated vector of dispersal graphs (Fig. 3 and Supplementary Fig. S8 available on Dryad). Because area adjacencies are abiotic palaeogeographical features, and because the biogeographic model estimates how severely palaeogeographic adjacency constrains species dispersal, the model is generally appropriate for use with other terrestrial clades.

Through simulation, I showed that biogeographic dating identifies clade age from the rates of molecular and biogeographic character change. Following that, the simulation framework could easily be extended to investigate for what phylogenetic, palaeogeographic, and biogeographic conditions one is able to reliably extract information for the root age. For example, a clade with taxa invariant for some biogeographic state would contain little to no information about root age, provided the area has always existed and had a constant number of dispersal edges over time. At the other extreme, a clade with a very high dispersal rate or with a proclivity toward long-distance dispersal might provide little information due to signal saturation (Supplementary Figs. S2e,f available on Dryad). The breadth of applicability of biogeographic dating will depend critically on such factors, but because we do not expect to see closely related species uniformly distributed about Earth nor in complete sympatry, that breadth may not be so narrow.

After validating the method through simulation, I tested whether divergence times might be estimated from extant taxa in an empirical system, Testudines. I assumed a flat root age calibration prior for the origin time of turtles: the posterior root age was also flat when palaeogeography was ignored, but Pangaeanean times of origin were strongly preferred when dispersal rates conditioned on palaeogeography (Fig. 7). Under the uninformative prior distributions on root age, biogeographic dating estimated turtles originated between the Late Devonian (358 Ma) and Early Cretaceous (135 Ma) epochs, with a posterior median age of 219 Ma. Under an ignorance prior where the prior to strongly prefer short-distance dispersal. Both dispersal modes are strongly favored over long-distance dispersal. Posterior estimates changed little by informing the prior to strongly prefer short-distance dispersal. Both short- and medium-distance dispersal modes are strongly favored over long-distance dispersal. Posterior estimates changed little by informing the prior to strongly prefer short-distance dispersal. Both with and without root age calibrations, and with both flat and informative dispersal mode priors, biogeographic dating placed the posterior median origin time of turtles at approximately 220–200 Ma, which is consistent with fossil-based estimates (Fig. 8), albeit with less precision.

The increased uncertainty in the root age estimates under biogeographic dating may be caused by any combination of possible factors. First, in the absence of fossils, biogeographic events are historical and not observed directly. Through inference, all possible biogeographic scenarios are assigned plausibility in terms of their likelihoods, which inherently

introduces uncertainty that any one history occurred. By comparison, turtle fossils can be placed with relatively high phylogenetic and temporal certainty, and thus produce more precise estimates. Second, the model and priors are designed to contrast how well biogeographic dating (+G) estimates divergence times relative to a state of complete geographical ignorance (−G). For example, using a time-homogeneous birth–death process prior will cause divergence events to follow a more clock-like pattern, which is likely to be more realistic than a uniform time tree prior, which has high node age variance by design. Additional fossil node calibrations were available for use from Joyce et al. (2013), but they induce a non-uniform root age prior distribution (Warnock et al. 2015), and would have complicated the interpretation of the results. Better behaved priors are available and recommended for rigorous empirical investigations. Third, limited by the availability of genetic data, only 385 of over 300 extant teststudies were used in the analysis. Increased taxon sampling generally improves ancestral state estimation (Heath et al. 2008), which will translate to improved node age estimation for biogeographic dating. Fourth, process-based dating methods are sensitive to the underlying model assumptions (O’Reilly et al. 2015), and, in the section to come, I explore how model inadequacies might affect biogeographic dating.

Nonetheless, biogeographic dating generates relative and uncertain root age estimates when compared to previously published fossil-based results on a per-study basis. The nine fossil-based estimates were produced using diverse techniques (Figure 8): four were estimated with node-dating (Warnock et al. 2015; Alfaro et al. 2009; Joyce et al. 2013; Dornburg et al. 2011), three with maximum parsimony (Sterli et al. 2013; Joyce 2007; Danilov and Parham 2008), and two with penalized likelihood rate smoothing (Hugall et al. 2007; nucleotides and amino acids). Among these studies, the average support interval width is approximately 45 Ma while their combined supported root ages are over three times as wide, ranging from 145 Ma at the youngest to 324 Ma at the oldest (width 179 Ma). On this note, at least three of the nine fossil-based root age estimates must be incorrect due to the poor support interval overlap. For dating exercises, it is worth noting that precision should not be maximized for its own sake. Uncertainty is valuable when it is correctly measured and guards against being positively incorrect. That said, the combined fossil-based support interval (145 Ma to 324 Ma) is still 31% narrower than the supported ages reported across the biogeographic dating analyses (100 Ma to 358 Ma, width 258 Ma, excluding −G analyses).

Exercises comparing performance between fossil-based and biogeographic-based dating are left for future work. However, fossil-based and biogeography-based dating methods should not be viewed as competitive, since nothing inherently prevents them from being applied simultaneously to further improve precision. For example, under the design of the earlier biogeographic dating analysis, adding a root age prior effectively truncates the posterior density (Figure 7), thus allowing fossil-based hypotheses to tune the precision of root age estimates.

For groups with poor fossil records, biogeographic dating provides a second hope for dating divergence times. Since biogeographic dating does not rely on any fossilization process or data directly, it is readily compatible with existing fossil-based dating methods (Figure 7). When fossils with geographic information are available, researchers have shown fossil taxa improve biogeographic inferences (Moore et al. 2008; Mao et al. 2012; Nauheimer et al. 2012; Wood et al. 2012; Meseguer et al. 2015). In principle, the processes of morphological and biogeographic evolution should guide placement of fossils on the phylogeny, and the age of the fossils should improve the certainty in estimates of ancestral biogeographic states (Slater et al. 2012), on which biogeographic dating relies. A joint tip-dated and biogeography-dated analysis under the fossilized birth–death process (Gavryushkina et al. 2015; Zhang et al. 2015) would produce improved node age estimates in a methodologically consistent framework. Joint inference of divergence times, biogeography, and fossilization stands to resolve recent paleobiogeographic conundrums that may arise when considering inferences separately (Beaulieu et al. 2013; Wilf and Escapa 2014).

Model Inadequacies and Future Extensions

The simulated and empirical studies demonstrate biogeographic dating improves divergence time estimates, with and without fossil calibrations, but many shortcomings in the model remain to be addressed. When any model is misspecified, inference is expected to produce uncertain or, worse, spurious results (Lemmon and Moriarty 2004), and biogeographic models are not exempted. Because the biogeographic model assumed in the analysis is so very simple, a rigorous battery of simulation studies must be carried out to assess the method’s robustness when faced with model violation. To this end, I discuss some of the most apparent model misspecifications below.

Anagenetic range evolution models that properly allow species to inhabit multiple areas should improve the informativeness of biogeographic data. Imagine taxa $T_1$ and $T_2$ inhabit areas $ABCDE$ and $FGHIJ$, respectively. Under the simple model assumed in this article, the tip states are ambiguous with respect to their ranges, and for each ambiguous state only a single dispersal event is needed to reconcile their ranges. Under a pure anagenetic range evolution model (Rhee et al. 2005), at least five dispersal events are needed for reconciliation. Additionally, some extant taxon ranges may span ancient barriers, such as a terrestrial species found both north and south of the Isthmus of Panama. When multiple-area ranges are used, this situation almost certainly requires a dispersal event to have occurred after the isthmus was formed. For single-area species ranges coded as ambiguous states, the model effectively takes
the weighted average of the lineage being only north and being only south of the isthmus, so information about the effects of the paleogeographical event on divergence times will be relatively diluted.

Any model where the diversification process and paleogeographical states (and events) are correlated or co-occurring will obviously improve divergence time estimates so long as that relationship is biogeographically realistic. Although the repertoire of cladogenetic models is expanding in terms of types of transition events, they do not yet account for geographical features, such as continental adjacency or geographical distance. Incorporating paleogeographical structure into cladogenetic models of geographically isolated speciation, such as vicariance (Ronquist 1997), allopatric speciation (Ree et al. 2005; Goldberg et al. 2011), and jump dispersal (Matzke 2014), is crucial not only to generate information for biogeographic dating analyses, but also to improve the accuracy of ancestral range estimates. Ultimately, cladogenetic events are state-dependent speciation events, so the desired process would model range evolution jointly with the birth-death process (Maddison et al. 2007; Goldberg et al. 2011), but inference under these models for large state spaces is currently infeasible. Regardless, any cladogenetic range-division event requires a widespread range, which in turn implies it was preceded by dispersal (range expansion) events. Thus, if we accept that paleogeography constrains the dispersal process, even a simple dispersal-only model will extract dating information when describing a far more complex evolutionary process.

That said, the simple paleogeographical model described herein (section “Adjacent-Area Terrestrial Dispersal Graph”) has many shortcomings itself. It is only designed for terrestrial species originating in the last 540 Ma. The number of epochs and areas was limited by my ability to comb the literature for well-supported paleogeological events, while constrained by computational considerations (see Supplementary Material available on Dryad). The timing of events was assumed to be known perfectly, despite the literature reporting ranges of estimates. Rates of dispersal between areas are classified into short, medium, and long distances, but using necessarily practical and subjective criteria. Factors such as temperature, precipitation, ocean currents, ecoregion type, distances between areas, sizes of areas, carrying capacities, etc. certainly affect dispersal rates between areas in terms of magnitude and symmetry, and in terms of the stationary frequencies per epoch, but were ignored. These factors may be integrated into the existing paleogeographical model so long as the data are available. From the modeling perspective, the rate matrix equation (Equation 1) can accommodate additional layers of historical features, such as those listed above, through additional weight parameters and rate matrix vectors. Regarding how to incorporate those features, Sanmartín et al. (2008) suggest how the biogeographic rate matrix may encode various celebrated colonization models (MacArthur and Wilson 1967; Hanski 1994). Finally, these colonization rates are likely to interact with the evolving life history traits intrinsic to each lineage, such as flightedness or cold tolerance, as modeled by Sukumaran et al. (2015). All of these factors can and should be handled more rigorously in future studies by modeling these processes and factors as part of a joint Bayesian analysis (Höhna et al. 2014).

Despite these flaws, defining the paleogeographical model serves as an exercise to identify what features allow a biogeographic process to inform speciation times. Identifying significant areas and epochs remains challenging, where presumably more areas and epochs are better to approximate continuous space and time, but this is not without computational challenges (Ree and Sanmartin 2009; Webb and Ree 2012; Landis et al. 2013). Dispersal barriers are clearly clade-dependent and depend on various life history traits, for example, benthic marine species dispersal would be poorly modeled by the terrestrial graph. Classifying dispersal edges into dispersal mode classes may be made rigorous using clustering algorithms informed by paleogeographical features, or even abandoned in favor of modeling rates directly as functions of paleogeographical features like distance. Rather than fixing epoch event times to point estimates, one might assign empirical prior distributions based on collected estimates. Ideally, paleogeographical event times and features would be estimated jointly with phylogenetic evidence, which would require interfacing phylogenetic inference with paleogeographical inference. Following Sanmartín et al. (2008), multi-clade biogeographic analyses could be used to generate the statistical power necessary to obtain reliable paleogeographical estimates. This would be a profitable, but substantial, interdisciplinary undertaking.

**Conclusion**

Historical biogeography is undergoing a probabilistic renaissance, owing to the abundance of georeferenced biodiversity data now hosted online and the explosion of newly published biogeographic models and methods (Ree et al. 2005; Ree and Smith 2008; Sanmartín et al. 2008; Lemmon and Lemmon 2008; Lemey et al. 2010; Goldberg et al. 2011; Webb and Ree 2012; Landis et al. 2013; Matzke 2014; Sukumar and et al. 2015; Tagliacollo et al. 2015). Making use of these advances, I have shown how patterns latent in biogeographic characters, when viewed with a paleogeographic perspective, provide information about the geological timing of speciation events. The method conditions directly on biogeographic observations to induce dated node age distributions, rather than imposing (potentially incorrect) beliefs about speciation times using node calibration densities, which are data-independent prior densities. Biogeographic dating may present new opportunities for dating phylogenies for fossil-poor clades since the technique requires no fossils. This establishes that historical
biogeography has untapped practical use for statistical phylogenetic inference, and should not be considered of secondary interest, only to be analyzed after the species tree is estimated.
