Despite the well-accepted notion that early maternal influences persist beyond fetal life and may underlie many adult diseases, the risks imposed by the maternal environment on breast cancer development and underlying biological mechanisms remain poorly understood. In this study, we investigated whether early exposure to blueberry (BB) via maternal diet alters oncogene Wnt1-induced mammary tumorigenesis in offspring. Wnt1-transgenic female mice were exposed to maternal Casein (CAS, control) or blueberry-supplemented (CAS + 3%BB) diets throughout pregnancy and lactation. Offspring were weaned to CAS and mammary tumor development was followed until age 8 months. Tumor incidence and latency were similar for both groups; however, tumor weight at killing and tumor volume within 2 weeks of initial detection were lower (by 50 and 60%, respectively) in offspring of blueberry-fed dams. Dietary BB exposure beginning at weaning did not alter mammary tumor parameters. Tumors from maternal BB-exposed offspring showed higher tumor suppressor Pten and Cdh1 and lower proiferative Ccnd1, anti-apoptotic Bcl2 and proangiogenic Fgf, Flt1 and Ephb4 transcript levels, and displayed attenuated microvesSEL density. Expression of Pten and Cdh1 genes was also higher in mammary tissues of maternal BB-exposed offspring. Mammary tissues and tumors of maternal BB-exposed offspring showed increased chromatin-modifying enzyme Dmnt1 and Ezh2 transcript levels. Body weight, serum insulin and serum leptin/adiponectin ratio were lower for maternal BB-exposed than control tumor-bearing offspring. Tumor weights and serum insulin were positively correlated. Results suggest that dietary influences on the maternal environment contribute to key developmental programs in the mammary gland to modify breast cancer outcome in adult progeny.

Introduction

The concept that the risk of adult diseases is partially established in the womb (i.e. fetal origin of adult diseases) was initially advanced by Professor David Barker for coronary heart disease in the 1980s (1). Since this seminal (and highly provocative) report, many epidemiological studies have linked poor maternal health to subsequent detrimental health effects in adult offspring (2–4). Nevertheless, the mechanisms underlying these life-long linkages, by which limited exposure (less than a year) to a non-supportive maternal environment may affect susceptibility to many devastating adult diseases, such as diabetes and cancer, are essentially unknown (5).

Breast cancer is the second leading cause of cancer-related deaths and the most common malignancy among women (6). Although this complex disease exhibits prominent genetic underpinnings (7), there is growing acceptance that susceptibility to breast cancer may be partly predetermined in utero (8). Initial support for this concept came from findings of increased breast cancer risk in daughters of women who used the synthetic estrogen diethylstilbestrol during pregnancy (9,10). Diet-related modifiable risks for breast cancer. Maternal exposure to dietary components has been reported to elicit significant effects on mammary gland development and breast cancer outcome in offspring in rodent models. For example, female rat offspring exposed to a maternal high-fat diet during gestation have higher incidence of and larger mammary tumors when administered the carcinogen 7,12-dimethylbenz[a]anthracene as young adults (11,12). A fat-enriched maternal diet similarly increased spontaneous mammary tumor formation in outbred mice (13) and in transgenic mice overexpressing c-neu oncogene (14). Protein restriction during pregnancy and lactation resulted in early onset of mammary tumorigenesis (by 2-fold) in rat offspring after N-methyl-N-nitrosourea administration (15). Further, agouti mice exposed to soy isoflavone genistein early in life via maternal diet were more likely to adopt a ‘healthy’ pseudoagouti rather than the ‘disease-prone’ yellow agouti phenotype (16). Our own studies showed that in utero and lactational exposure to a soy protein diet increased the latency and decreased the multiplicity of N-methyl-N-nitrosourea-induced mammary tumors in rat offspring (17). These protective effects were partly mediated by increased expression of the tumor suppressor E-cadherin in the mammary gland prior to carcinogenic insult. Nonetheless, whereas pharmacological agents, carcinogens and other environmental endocrine disruptors (e.g. high estrogen concentrations) are known to disrupt the normal course of mammary gland development via their gene-altering activities (18), a clear understanding of how maternal nutritional history and specifically, how maternal consumption of diets readily available to the Western population may predispose to breast cancer risk upon fetal exposure, is yet to be achieved.

To further explore the role of maternal diet in breast cancer outcome of adult progeny following fetal/neonatal exposure and potential underlying mechanisms, we evaluated the effects of whole blueberry (BB) powder consumed by pregnant and lactating dams on mammary tumor incidence and progression in their offspring. Our study used MMTV-Wnt1-transgenic (Wnt1-Tg) mice that overexpress the oncogene Wnt1 in the mammary gland (19). Although mutations in Wnt components are rarely seen in women with breast cancer, with the exception of metastatic breast carcinoma (20), overexpression of Wnt1 leads to increased β-catenin nuclear pools, a feature of >50% of human breast carcinomas (21). In a previous study, we showed enhanced prepubertal mammary gland differentiation in female rat offspring of dams consuming BB diet (22), although mammary tumor parameters were not evaluated. Recently, dietary intake of whole BB powder was shown to elicit anti-tumor and anti-metastatic activity in nude mice when transplanted with MDA-MB-231 triple negative breast cancer cells (23). Further, studies in humans (24) and rodents (25) demonstrated that dietary BB supplementation inhibited obesity-associated insulin resistance, in part by decreasing inflammation.

In this study, we tested the hypothesis that fetal and lactational exposure
to maternal BB-supplemented diet will suppress mammary tumor incidence and/or progression in adult offspring through effects on critical oncogenic and metabolic (insulin) signaling pathways, and which may involve altered expression of key DNA-modifying enzymes.

Materials and methods

Animals and diets

Animal studies were performed in compliance with protocols approved by the University of Arkansas for Medical Sciences Institutional Animal Care and Use Committee. Animals were housed in polycarbonate cages under conditions of 24°C, 40% humidity and a 12 h light, 12 h dark cycle. Wnt1-Tg male mice [B6SJ-Tg(Wnt1)1Hef/J] were purchased from Jackson Laboratories (Bar Harbor, ME) and mated with wild-type (WT) females of the same strain to generate female Wnt1-Tg offspring. In Study 1, WT dams were randomly assigned to one of two diets prior to mating: (i) American Institute of Nutrition-93G-based pelleted diet containing casein (CAS) as the major protein source (Harlan, Indianapolis, IN) and (ii) CAS to which was added freeze-dried whole wild BB (Vaccinium angustifolium) powder (generous gift of the Wild Blueberry Association of North America, courtesy of Susan Davis) at 3% by weight of feed (designated BB). Supplementary Table 1, available at Carcinogenesis Online describes the preparation and processing of the composite BB powder, its average total anthocyanin content and relative anthocyanin concentrations. Diet with added BB powder was formulated to be isoeenergetic and isounitropic, with 7% BB powder, its average total anthocyanin content and relative anthocyanin concentrations.

Mammary tissue collection and tumor analyses

Mammary gland pairs 2, 3 and 4 were harvested from PND21 (WT and Wnt1-Tg) and PND50 (WT) mice and used for analyses as follows. The left inguinal and mammary gland (4) was fixed for whole-mount analyses, whereas the corresponding right gland (with lymph nodes removed) was immediately homogenized in Trizol (Invitrogen, Carlsbad, CA) for RNA analyses (below). The right-halves of mammary glands 2 and 3 were snap frozen at −80°C for western blot analyses. Wnt1-Tg mice were palpated twice weekly from 4 weeks of age to monitor tumor formation. Tumors were measured using a digital caliper for length, width and height at initial detection and 2 weeks later were excised, weighed and re-measured. Tumor volume was calculated using the standard calculation for a sphere ([4/3 × 3.14 × a^3]) (26). Tumors were divided into three parts: one part was processed for immunohistochemistry and pathology, the second was reserved for whole-mount analyses and the third was stored at −80°C for protein analyses.

Microvessel density analysis

Microvessel density was determined in tumors from Wnt1-Tg mice (n = 3–4 per diet group) as described previously (27). Microvessels were immunolabeled with rat anti-mouse CD34 (AbD-serotec, Kidlington, UK) at 1:25 dilution, followed by biotinylated rabbit anti-rat IgG at 1:100 dilution (Vector Laboratories, Burlingame, CA). Staining was visualized using Vectastain Elite ABC kit followed by Vector DAB substrate kit as per manufacturer’s instructions (Vector Laboratories). Sections were lightly stained with hematoxylin. Stained tissue sections were scanned by Aperio ScanScope (Aperio Technologies, Vista, CA) to capture high resolution digital images of the entire section. Vessels were counted in five random areas of tumor infiltration (1 mm²/area) per tumor sample in a blinded fashion.

Results

Dietary exposure to BB through maternal diet altered mammary parameters in offspring

Whole mounts of fat pads were prepared from WT and Wnt1-Tg female offspring of dams that were fed control (CAS) or BB-supplemented (BB) diets during pregnancy and lactation (Figure 1A). At weaning (PND21), mammary glands from Wnt1-Tg offspring of CAS-fed dams displayed extensive ductal side-branching and highly developed lobuloalveoli structures (Figure 1B). In contrast, mammary glands from WT littermates (Figure 1B) showed rudimentary branching and distinct TEBs, with no detectable alveoli. The extensive mammary hyperplasia

Maternal dietary programming of mammary tumor outcome

Whole mounts of fat pads were prepared as described (22) and evaluated under a dissecting microscope. The total numbers of terminal end buds (TEBs) located at the leading edge of the fat pad, were counted from whole mounts of the left mammary gland 4; four to five mice were used for each diet group. Branching density for each gland was quantified by counting the number of branched points within a box of fixed dimensions (22). Histopathology of tumors from hematoxylin–eosin stained paraffin sections (17) was determined by a residency-trained veterinary pathologist (L.J.H.) using accepted criteria established by an expert panel of surgical, veterinary and experimental pathologists (28). Immunostaining for cyclin D1 used anti-cyclin D1 antibody (1:250 dilution; Santa Cruz Biotechnology, Santa Cruz, CA) following the manufacturer’s protocols. Sections of solid carcinoma tumors from four individual mice per diet group were analyzed. Negative controls were tumor sections processed in parallel, except with the omission of primary antibody.

Quantitative real-time PCR

Total RNA isolation, preparation of corresponding cDNAs and quantitative real-time PCR (qPCR) analyses followed previously described protocols (29). Primers (Supplementary Table 3, available at Carcinogenesis Online) were designed to span introns, using Primer Express software (Applied Biosystems, Foster City, CA) and were synthesized by Integrated DNA Technologies (Coralville, IA). The expression of each target mRNA was calibrated to a standard curve generated using pooled cDNAs and normalized to that of TATA-box binding protein (Tbp).

Western blot analyses

Whole cell lysates and nuclear extract proteins were prepared from frozen mammary tumors and subjected to immunoblotting as described previously (30). Primary antibodies used were anti-PTEN (1:1000; Cell Signaling, Danvers, MA), anti-cyclin D1 (1:400; Santa Cruz Biotechnology), anti-DNMT1 (1:1000; Abcam, Cambridge, MA), anti-EZH2 (1:1000; Cell Signaling) and anti-β-actin (1:2000; Sigma Chemical Co., St Louis, MO). The immunoreactive proteins were visualized with the Amersham ECL Plus kit (GE Healthcare Life Sciences, Piscataway, NJ). Digital images were captured using the GE Image Scanner III detection system and quantified using Quantity One software (Bio-Rad Laboratories, Hercules, CA).

Serum hormone assays

The levels of insulin and leptin in sera of Wnt1-Tg mice displaying solid carcinoma tumors 2 weeks post initial tumor detection (Study 1: n = 9 individual mice per diet group) were measured using the Milliplex MAP mouse serum adipokine kit (Millipore Corp., Billerica, MA), following the manufacturer’s instructions. For insulin and leptin assays, the sensitivity thresholds were 24.9 and 3.7 pg/ml, respectively, whereas intra- and interassay coefficients of variations were <4.5 and 10.3%, respectively. Serum insulin levels for mice in Study 2 (n = 8–9 individual mice per diet group) were measured using the Rat/Mouse Insulin ELISA kit (Millipore); sensitivity was 0.2 ng/ml and intra- and interassay coefficients of variations were 5 and 11%, respectively. Serum adiponectin concentrations were measured using a mouse adiponectin ELISA kit (Millipore Corp.). Adiponectin assay sensitivity was 0.5 ng/ml and intra- and interassay coefficients of variations were <5%. Serum IGF-1 levels were measured using the Mouse/Rat IGF-1 immunoassay kit (R&D Systems, Minneapolis, MN), with a sensitivity threshold of 1.6 pg/ml.

Data analyses

Data are presented as mean ± SEM and were compared by t-test or one-way analysis of variance, using SigmaStat version 3.5 Software (SPSS, Chicago, IL). Differences in tumor incidence between diet groups were determined by Fisher Exact test. P ≤ 0.05 was considered to be statistically significant.
elicted by Wnt1 overexpression in PND21 Wnt1-Tg offspring precluded an accurate determination of differences in mammary branching and TEB numbers with diet. To determine whether maternal diet affected mammary gland development, whole mounts of fat pads from young adult (PND50) WT female pups were weaned to CAS diet. Inguinal mammary gland (4) was collected for RNA (right MG) and whole mount (left MG) from weaning (PND21) pups. For the tumor study, Wnt1-Tg female offspring that were exposed via maternal diet to either CAS (n = 33) or BB (n = 28) were monitored weekly by palpation for tumor development. Two weeks post-tumor detection, serum was collected and tumors were harvested for RNA and protein analyses. (B) Whole-mount analysis revealed excessive branching and hyperplasia in mammary glands of Wnt1-Tg female pups at weaning (PND21), compared with WT mice, as previously reported (19). (C) Shown are the mammary glands of PND50 virgin WT female mice exposed to CAS or BB via maternal diet. (D) Ductal branching was quantified in PND21 and PND50 WT mice. (E) Quantification of mammary TEB in PND21 and PND50 WT mice exposed to maternal CAS or BB diets. Results are mean ± SEM; *P < 0.05 relative to CAS (n = 5 mice per diet, per PND). Bar, 300 µm. 3× magnification.

Female Wnt1-Tg offspring of dams that were fed CAS or BB diets during pregnancy and lactation were followed for mammary tumor onset up to age 8 months. Exposure to maternal BB diet did not alter mammary tumor incidence in these females, as determined by Kaplan–Meier analysis (Figure 2A). The average age of tumor onset (5–6 months) was comparable (P = 0.265) between offspring of both diet groups (Figure 2B). However, the change in tumor volume, defined as the percentage change in tumor size from initial detection to tumor harvest at 2 weeks postdetection, and tumor weights (measured at tumor harvest and normalized to body weights) were lower for offspring of the BB-fed dams (Figure 2C and D). Histopathological analyses of the tumors showed

Maternal dietary programming of mammary tumor outcome

Dietary BB exposure postweaning did not alter mammary tumor parameters

To determine if postweaning exposure to BB relative to the control diet, recapitulated the effects of early BB exposure through maternal diet, female Wnt1-Tg offspring of control (CAS) diet-fed dams were weaned (at PND21) to CAS or BB diets and monitored for tumors until age 8 months (Supplementary Figure 1A, available at Carcinogenesis Online). The incidence, onset, change in volume and weights of mammary tumors of Wnt1-Tg females fed BB diets did not differ from those of Wnt1-Tg females fed CAS (Supplementary Figure 1B–3E, available at Carcinogenesis Online). Diet did not affect the type of mammary tumors that developed (Supplementary Table 4, available at Carcinogenesis Online).

Gestational + lactational exposure to BB diet promoted tumor suppressor expression in mammary tumors

Solid carcinoma tumors from Wnt1-Tg offspring of dams that were fed CAS or BB diets (n = 9/diet group) were evaluated for expression of tumor suppressor (Pten; p53; cadherin 1, Cdh1), proliferative (Cyclin D1, Ccnd1; c-Myc) and anti-apoptotic (Bcl2, survivin) genes by QPCR. Transcript levels of Pten and Cdh1 were increased, whereas those of Ccnd1 and Bcl2 were decreased, in tumors of maternal BB-exposed offspring (Figure 3A). Diet did not influence expression of Wnt1, p53, c-Myc and survivin in tumors. The changes in gene expression for Pten and Ccnd1 in mammary tumors with exposure to maternal BB diet were confirmed at the protein level by western blots (Figure 3B). In contrast, transcript levels of enzymes involved

Maternal exposure to BB diet decreased microvessel density in mammary tumors of Wnt1-Tg offspring

To determine whether the lower tumor volume and weight seen with maternal exposure to BB diet (Figure 2C and D) could involve regulation of growth factor supply via the vasculature, tumor microvessel density was analyzed by CD34 immunostaining (Figure 4A). CD34-reactive microvessel numbers were 2-fold lower (CAS = 57.72 ± 12.1 versus BB = 28.04 ± 2.85; P = 0.039) in tumors from Wnt1-Tg mice exposed to maternal BB diet relative to the CAS-exposed group (Figure 4B). To evaluate possible mediators of the observed decrease in microvessel formation with maternal dietary BB exposure (Figure 4A and B), we measured the transcript levels of a panel of genes with known anti- and proangiogenic activities, in mammary tumors of Wnt1-Tg offspring. Tumors from offspring exposed to maternal BB diet relative to those exposed to control diet had higher expression of genes Col4a3 and Thbs1, which were shown previously to inhibit angiogenesis (31,32); no differences for Thbs2, Timp1 or Timp2 transcript levels were observed between the dietary groups (Figure 4C). Analysis of proangiogenic genes revealed suppression of Ephb4 (33), Figgf (34) and Flt1 (34) transcript levels in tumors from offspring with maternal BB exposure (Figure 4D). Similar changes in the expression of other proangiogenic genes such as Angpt1, Mmp2, Mmp9, Vegfa and Vegfc were not observed (Figure 4D).

Early exposure to BB diet altered gene expression of DNA methylation and chromatin-modifying enzymes in mammary tumors

To examine potential associations between maternal BB dietary effects on offspring mammary tumor outcome and epigenetic mechanisms, the expression patterns of a select group of DNA methylation and chromatin-modifying enzyme genes were evaluated in mammary tumors by QPCR. Transcript levels of DNA methyl transferase 1 (Dnmt1) and Enhancer of zeste homolog 2 (Ezh2) were higher in tumors from BB-exposed offspring (Figure 5A); these changes in transcript abundance were confirmed at the protein level by western blots (Figure 5B). In contrast, transcript levels of enzymes involved
Fig. 3. Tumors from Wnt1-Tg mice exposed to BB via maternal diet exhibit higher expression of anti-proliferative, proapoptotic and prodifferentiation markers. (A) Genes involved in cell proliferation, apoptosis, differentiation and tumor progression were evaluated by QPCR in tumors from Wnt1-Tg mice exposed to CAS or BB diets in utero and during lactation. Tbp was used as a normalizing control; *P < 0.05 relative to CAS (n = 9 per diet group). (B) Western blot analysis of PTEN and cyclin D1 proteins in CAS or BB tumors. Each lane (50 µg of total protein) represents an individual animal. (C) Immunoreactive bands (in B) were quantified by densitometry. Normalized values relative to β-actin are presented as histograms (*P < 0.05 relative to CAS). (D) Representative cyclin D1 immunostaining of CAS and BB tumors from five tumored mice (per diet group) is shown at ×200 magnification. Each panel for CAS and BB represents solid carcinoma tumor sections (Supplementary Table 4, available at Carcinogenesis Online) from an individual mouse. Negative control shows lack of immunostaining in the absence of primary antibody. Bar, 100 µm.
Maternal dietary programming of mammary tumor outcome

in histone modifications namely histone deacetylases 1, 2, 3 and 9 (Hdac1, 2, 3 and 9) were not influenced by diet (Figure 5A).

Preneoplastic mammary tissues of PND21 Wnt1-Tg female offspring of the two diet groups were similarly evaluated for changes in expression of tumor suppressor Pten and Cdh1, pro proliferative Ccnd1 and DNA/chromatin-modifying enzyme (Dnmt1, Ezh2, Hdac3, 6 and 9) genes, by QPCR. The increase in Pten, Cdh1, Dnmt1 and Ezh2 transcript levels in mammary tumors of maternal BB-exposed offspring was also observed in corresponding non-tumor PND21 mammary tissues (Figure 5C and 5D). In contrast to mammary tumors,
preneoplastic mammary tissue Ccnd1 transcript levels did not differ, whereas those for Hdac3 and Hdac9 were greater with maternal BB exposure. Diet did not alter Wnt1 gene expression in tissues (Figure 5C), as shown for mammary tumors (Figure 3A).

Maternal diet influenced body weight and hormone levels in tumored offspring

To determine if maternal diet affected endocrine parameters that may influence mammary tumor development long after the dietary exposure, body weights of offspring were evaluated throughout the study, and serum levels of the adipokines leptin and adiponectin and of insulin and IGF-1 were measured in tumored mice at killing. Although body weights of offspring from the two diet groups did not differ at weaning, lower body weights were found for maternal BB-exposed Wnt1-Tg females by PND50 and which persisted for lifetime, when compared with maternal CAS-exposed counterparts (Figure 6A). BB-exposed, tumor-bearing offspring showed numerically lower serum leptin/adiponectin ratio (Figure 6B), and significantly reduced serum insulin levels (Figure 6C). Serum IGF-1 levels did not differ for offspring of the two groups (CAS: 443.47 ± 23.75 ng/ml; BB: 426.11 ± 52.19 ng/ml). Tumor weights were positively correlated with serum insulin levels (R = 0.46; Figure 6D). Interestingly, although mice exposed to BB diets beginning at postweaning had lower body weights than those of CAS-fed mice (Figure 6E), serum insulin levels for mice in these two groups did not differ (Figure 6F).

Discussion

This study provides strong support for the significant influence of maternal diet on mammary tumor outcome in progeny. Using the Wnt1-Tg mouse model of spontaneous human breast cancer and BB powder intake at 3% of the diet, amounts which are readily achievable with half to one cup of BBs per day for an average-weight individual, we showed that maternal BB consumption during pregnancy
Maternal dietary programming of mammary tumor outcome

and lactation elicited reductions in mammary tumor weight and tumor volume in adult progeny, resulting in a more favorable prognosis. The suppression of mammary tumor growth with early BB exposure, which was not recapitulated when the same BB diet was introduced during early childhood (postweaning) and continued through adulthood, suggests that the effects of early BB exposure with later adult...
consequence, probably occurred during an early window of mammary gland development. We further showed that the inhibitory effects of early BB exposure on mammary tumor growth are associated with: (i) elevated expression of tumor suppressors PTEN and E-cadherin and lower expression of anti-apoptotic Bcl2 and proliferative cyclin D1, genes in mammary tumors; (ii) an early increase (at weaning) of PTEN and E-cadherin gene expression in mammary tissues, which was accompanied by reduced ductal side-branching in developing (PND21) and young adult (PND50) young adult (PND50) mammary glands, respectively, and (iii) decreased intratumoral microvessel density and decreased and increased expression, respectively, of a subset of pro- and anti-angiogenic genes. The differences in ductal branching with early BB exposure are not likely due to differing estrous cycle stage at the time of tissue collection because these were observed even at PND21, when these mice have not begun to cycle. Moreover, we previously demonstrated that exposure to BB through maternal diet did not promote sexual maturity (22).

We provided evidence to suggest that the effects of early dietary BB exposure on gene expression patterns in preneoplastic mammary tissues and mammary tumors may involve epigenetic modifications through early BB effects on EZH2 and DNMT1 expression, both of which regulate the expression of many developmental genes (36). Finally, we showed that the long-term effects of maternal BB diets are associated with altered metabolic parameters in offspring, manifested as decreased body weights, lower serum insulin levels and diminished leptin/adiponectin ratio, all of which are negatively linked to breast cancer progression (37–39).

In this study, we utilized Wnt1-Tg female mice as an in vivo model for human breast cancer because numerous targets of the Wnt signaling pathway are overexpressed or deregulated in breast tumors (40). Moreover, we have previously demonstrated that tumor suppressors PTEN and E-cadherin, which are linked by their regulation of β-catenin degradation and nuclear transport (41,42), are in vivo and in vitro targets of diets/dietary factors with breast cancer protective effects (29,30,43,44). Although maternal BB diet did not reduce Wnt1-induced tumor incidence, most likely because highly activated Wnt signaling is a powerful driver of breast cancer initiation (19) and activation of this pathway could not be inhibited or reversed by bioactive components present in BB, limited early exposure to this diet was sufficient to alter the trajectory of mammary tumor volume/weight in offspring. The latter suggests the protective effects of early exposure to BB on pathways involved in tumor progression. The lack of a similar ‘rescue’ of overactivated Wnt signaling by provision of the BB diet at postweaning and through adulthood, suggests that a critical mechanism(s) and the precise mediators by which maternal BB exposure to BB in mammary tissues and tumors using more advanced methods and techniques will be necessary to fully understand the underlying biological processes involved in the observed effects.

In conclusion, our use of the Wnt1-Tg mouse model of human breast cancer has provided compelling support for the maternal (in utero/lactational) environment of the developing mammary gland as a modifiable determinant of breast tumor growth/progression in adult progeny. In light of the life-long effects of the limited (maternal only) dietary exposure described here, the notion of pubertal mammary
development as most susceptible to 'tumorigenic insults' may need reconsideration. Given the many health risks that can be imposed by obesity and poor dietary choices of pregnant and nursing mothers on their progeny, further studies on nutritional epigenomics and programming and how these may underlie breast cancer outcome and influence treatment of the disease are warranted.
