Abstract

Introduction: Hypertension is one of the most common clinical features of patients with overt and subclinical hypercortisolism. Although previous studies have shown the coexistence of autonomous cortisol and aldosterone secretion, it is unclear whether aldosterone plays a role in hypertension among patients with hypercortisolism. Therefore, we examined the associations of plasma aldosterone concentrations (PAC) with hypertension among patients with overt and subclinical hypercortisolism.

Methods: This single-center retrospective cohort study included patients with adrenal tumor and serum cortisol levels after 1-mg dexamethasone suppression test >1.8 µg/dL (50 nmol/L). Using multivariable regression models adjusting for baseline characteristics, we investigated the association of PAC with systolic blood pressure and post-operative improvement of hypertension after the adrenalectomy.

Results: Among 89 patients enrolled in this study (median age: 51 years), 21 showed clinical signs of Cushing’s syndrome (overt hypercortisolism) and 68 did not show clinical presentations (subclinical hypercortisolism). We found that higher PAC was significantly associated with elevated systolic blood pressure among patients with subclinical hypercortisolism (adjusted difference [95%CI] = +0.59 [0.19-0.99], p=0.008) but not among those with overt hypercortisolism. Among 33 patients with subclinical hypercortisolism and hypertension who underwent adrenalectomy, the postoperative improvement of hypertension...
was significantly associated with higher PAC at baseline (adjusted risk difference [95%CI] =
+1.45% [0.35-2.55], p-value=0.01).

**Conclusions:** These findings indicate that aldosterone may contribute to hypertension among
patients with subclinical hypercortisolism. Further multi-institutional and population-based
studies are required to validate our findings and examine the clinical effectiveness of the
intervention targeting aldosterone for such patients.

**Key Words:** Subclinical hypercortisolism; Aldosterone; Hypertension; Adrenalectomy.

**Introduction**

Cortisol production in the adrenal gland is regulated by the hypothalamus-pituitary-adrenal
(HPA) axis. Subclinical hypercortisolism is a status characterized by the alteration of HPA
axis secretion without typical signs or symptoms of overt hypercortisolism (e.g., moon face,
truncal obesity, easy bruising, thin extremities, proximal myopathy, cutaneous purple
striae).(1,2) While overt hypercortisolism can be detected by its clinical presentations or
severe complications, it is sometimes challenging for clinicians to appropriately diagnose
subclinical hypercortisolism due to the absence of such clinical presentations.(2) The 1 mg
overnight dexamethasone suppression test (1 mg-DST) measures the response of the adrenal
glands to adrenocorticotropic hormone (ACTH) through HPA axis, and therefore, has been widely used for screening and diagnosis of subclinical hypercortisolism.(1,3) The European Society of Endocrinology Guideline has defined a partial suppression of the HPA axis (i.e., serum cortisol levels after 1mg-DST [F-DST] >1.8 µg/dL [50 nmol/L]) without clinical signs of overt cortisol hypersecretion as “possible autonomous cortisol secretion”, and recommended screening these patients for metabolic disorders including hypertension and type 2 diabetes mellitus to offer appropriate treatment of these comorbidities.(4)

Hypertension is one of the most common and distinguishing clinical features in patients with subclinical hypercortisolism(2) as well as overt hypercortisolism.(5) Although hypertension can be triggered by excess cortisol levels,(5,6) it is still unclear whether even slightly elevated cortisol levels among individuals with subclinical hypercortisolism contribute to the occurrence of hypertension. This raises another potential mechanism to cause hypertension such as the co-existence of hyperaldosteronism; i.e., the excess of aldosterone that is an essential steroid hormone for sodium reabsorption, water retention, and blood pressure control.(7) Previous studies have reported that 10–20% of primary aldosteronism is accompanied by cortisol producing adenoma(8–10) and autonomous cortisol secretion was
decreased after the resection of the aldosterone-producing adenoma (a subtype of primary aldosteronism).(11) Furthermore, a previous mass spectrometry-based analysis revealed that cortisol secretion was frequently found in patients with primary aldosteronism.(12) Although these studies have examined cortisol biosynthesis in primary aldosteronism,(13) evidence about whether aldosterone plays a role in the occurrence of hypertension among people with subclinical hypercortisolism is limited.

To address this knowledge gap, we performed a cohort study examining the association between aldosterone and hypertension among patients with adrenal tumor and F-DST >1.8 µg/dL, stratified by whether patients had clinical signs of Cushing’s syndrome or not. We first analyzed the cross-sectional association between aldosterone and blood pressure at baseline. Then, we analyzed the longitudinal association between aldosterone at baseline and the improvement rate of hypertension after the adrenalectomy. Lastly, to further clarify the role of aldosterone in the regulation of blood pressure in subclinical hypercortisolism, we described the difference in aldosterone response to ACTH after the adrenalectomy according to the postoperative improvement of hypertension.
Methods

Data Sources and Study Participants

A retrospective cohort study was designed to assess the clinical characteristics (focusing on aldosterone) among patients with hypercortisolism at the Yokohama Rosai Hospital from 2008 to 2017. The data of this study are available from the corresponding author upon reasonable request. We enrolled 89 patients with adrenal tumor and F-DST > 1.8 µg/dL (50 nmol/L).(3,4,14) We then categorized them into two groups: (i) overt hypercortisolism (F-DST > 5.0 µg/dL [138 nmol/L] and having clinical signs of Cushing’s syndrome [moon face, central obesity, dorsocervical fat pad (buffalo hump), purple striae, thin skin, easy bruising, and proximal myopathy] (15) and (ii) subclinical hypercortisolism (not having such clinical signs). All patients with overt hypercortisolism in this study showed F-DST > 5.0 µg/dL (138 nmol/L). The study was approved by the research ethics committee of the Yokohama Rosai Hospital, and all participants provided written informed consent.

Measurements

Demographic characteristics were self-reported, and body mass index (BMI) was calculated using measured weight and height. Systolic blood pressure was measured in the sitting
position using a standard upper arm blood pressure monitor after a 5-minute rest in a quiet place. The mean of two measurements was recorded. If the measurement was done only once on a given occasion, the level obtained was recorded. When the patients were already taking antihypertensives at enrollment, they were asked to report their blood pressure levels at the diagnosis of hypertension (i.e., systolic blood pressure before starting antihypertensives). Blood samples were collected at 8:00 AM after the patient had rested in the supine position for 30 min. We measured serum cortisol levels (F, µg/dL, ×27.6 for nmol/L) and ACTH (pg/mL, ×0.220 for pmol/L) using chemiluminescent enzyme immunoassay (CLEIA) and electrochemiluminescent immunoassay (ECLIA), respectively. Plasma aldosterone concentrations (PAC, ng/dL, ×27.7 for pmol/L) and plasma renin activities (PRA, ng/mL/h) were measured using radioimmunoassay (RIA). Any antihypertensive drugs were replaced with calcium channel antagonists (including dihydropyridine calcium channel antagonists) and/or α blocker, several weeks before the measurement of PAC and PRA according to the clinical guideline of the Japan Endocrine Society (17). We also measured urine aldosterone (µg/day × 2.77 for nmol/day) and urine cortisol (µg/day, × 2.76 for nmol/day) using RIA. The tumor size was estimated using contrast-enhanced thin-section computed tomography (CT) scans of the adrenal glands.
To evaluate whether the patients have autonomous cortisol secretion, we performed 1-mg DST, in which dexamethasone (1 mg) was administered at 11:00 PM, and blood samples were drawn at 8:00 AM the following morning. F and ACTH were measured in 1-mg DST.

The total or partial adrenalectomy was performed in all cases with overt hypercortisolism. For patients with subclinical hypercortisolism, the adrenalectomy was recommended to those who showed F-DST > 5.0 µg/dL (138 nmol/L) accompanying metabolic disorders (3). It was also recommended to those who were expected to improve their clinical symptoms and/or metabolic disorders by the tumor resection, which included patients with hypertension possibly due to autonomous aldosterone secretion as well as autonomous cortisol secretion from the adrenal gland. The adrenalectomy was finally conducted when patients agreed with the treatment plan through informed consent. To evaluate whether patients have autonomous aldosterone secretion, we employed the screening criterion of primary aldosteronism (i.e. PAC/PRA ratio (ARR) > 20), followed by the confirmatory tests of primary aldosteronism including saline infusion test, captopril challenge, and/or furosemide stimulation test (17).
For patients who were considered to receive a benefit by the adrenalectomy and agreed with the examination, we performed the segment-selective adrenal venous sampling to assess the laterality of hyperaldosteronism (18–20). First, blood samples were collected from the bilateral central adrenal veins before ACTH stimulation. Then, we collected samples from the superior, lateral, and inferior tributaries of the right central adrenal vein and the superior and lateral tributaries of the left central adrenal vein after ACTH stimulation. Aldosterone excess (i.e., hyperaldosteronism) was considered when the effluent aldosterone concentrations were greater than 250 ng/dL before ACTH stimulation and 1400 ng/dL after ACTH stimulation, respectively (18–20). We used the absolute value instead of the lateralization index because individuals included in our study had the elevated cortisol concentrations given its inclusion criteria (i.e., F-DST >1.8 µg/dL [50 nmol/L]). For 9 patients with subclinical hypercortisolism who showed bilateral adrenal nodules, the side of adrenalectomy was determined by the nodule size and the results of adrenal venous sampling (i.e., laterality of hyperaldosteronism). The adrenalectomy was finally conducted when patients agreed with the treatment plan through informed consent. Immunohistochemical evaluation of aldosterone synthase cytochrome P450 (CYP11B2) was conducted for some resected nodules.
To evaluate the postoperative cortisol responsiveness to ACTH, we performed an ACTH stimulation test a year after the adrenalectomy, in which blood samples were collected and PAC and F were measured 30 and 60 min after ACTH administration. Postoperative improvement of hypertension was defined as blood pressure <140/90 mmHg without antihypertensives or the reduction of the number of antihypertensives to maintain blood pressure <140/90 mmHg after the adrenalectomy.

Statistical analyses

We described the demographic characteristics and endocrine parameters at baseline comparing patients with overt hypercortisolism and those with subclinical hypercortisolism, utilizing Fisher’s exact test for categorical variables and Mann-Whitney U test for continuous variables. Second, for each group, we investigated the association between the baseline characteristics and systolic blood pressure using ordinary least squares regression models. The model included age, sex, BMI, serum potassium levels, estimated glomerular filtration rate (eGFR), tumor size, F at 8:00 AM, and PAC at 8:00 AM. Third, we estimated the risk difference and 95% confidence interval (CI) of the improvement rate of hypertension after
the adrenalectomy according to these baseline characteristics (including systolic blood
pressure) using a modified least-squares regression model with a Huber-White robust
standard error (21). Lastly, to evaluate whether the improvement of hypertension is related to
postoperative cortisol and aldosterone secretion, we compared PAC and F responsiveness to
ACTH from peripheral blood samples between patients who improved hypertension and
those who did not using the Mann-Whitney U test. The longitudinal and postoperative
analyses were performed among patients with subclinical hypercortisolism because only 2
cases with overt hypercortisolism failed to show the improvement of hypertension after the
adrenalectomy.

To assess the robustness of our findings, we conducted the following two sensitivity analyses.
First, we replaced F at 8:00 AM with F after DST in our regression models. Second, we
estimated the risk difference of the improvement rate of hypertension after the adrenalectomy
according to the post-operative F and PAC levels after ACTH stimulation, adjusting for the
baseline characteristics included in our main model.

We also conducted several additional analyses. First, to investigate the relationship of change
in PAC after adrenalectomy with the improvement rate of hypertension, we included decrease in PAC between before and after adrenalectomy instead of PAC at baseline in the model.

Second, to assess the relationship between aldosterone and hypertension among patients with subclinical hypercortisolism without primary aldosteronism, we rerun the analyses excluding patients who met the diagnostic criteria of primary aldosteronism. Third, to understand the overall association, we rerun the analyses using all samples as a single group to assess the relationship among people with overall (i.e., overt and subclinical) hypercortisolism. Lastly, we compared PAC and F responsiveness to ACTH during adrenal venous sampling between patients with and without post-operative improvement of hypertension. All statistical analyses were performed using Stata version 15.

Results

Among the 89 enrolled patients, 21 showed clinical signs of overt Cushing’s syndrome and 68 did not show such clinical presentations. The flow of the study population is shown in Figure 1. Among 21 patients with overt hypercortisolism, 19 patients had hypertension. All patients underwent the adrenalectomy, and 16 patients showed the improvement of hypertension after the surgery (one patient was referred to another hospital, therefore no
information available). Among 68 patients with subclinical hypercortisolism, 63 patients had hypertension. After the evaluation of autonomous aldosterone secretion as well as autonomous cortisol secretion, 33 patients who underwent adrenalectomy with 23 patients (70%) showing the improvement of hypertension after the adrenalectomy (10 patients with surgery indication decided not to undergo adrenalectomy). Patients with subclinical hypercortisolism who underwent adrenalectomy showed lower PRA and higher ARR than those without adrenalectomy (Supplementary Table 1)(22).

Demographic characteristics and endocrine parameters among patients with overt and subclinical hypercortisolism

The median age (interquartile range) was 51 years (46–62 years), and 72% were female. Patients with overt hypercortisolism were relatively younger and showed higher eGFR and larger tumor size compared to patients with subclinical hypercortisolism (Table 1). Other demographic characteristics were similar between these groups. Patients with overt hypercortisolism showed higher F with undetected low ACTH, higher F after DST, and higher urine cortisol levels compared to those with subclinical hypercortisolism who instead showed higher PAC, and ARR. Among patients with subclinical hypercortisolism, 9/68
(13.2%) showed undetectable ACTH levels, and 25/68 (36%) showed positive for PA screening criterion (i.e., PAC/PRA ratio (ARR) > 20) followed by at least one positive confirmatory test. Based on the results of adrenal venous sampling of these cases, 9 showed aldosterone excess in the right nodules, 6 showed aldosterone excess in the left nodules, and 7 showed aldosterone excess on both sides, respectively (3 cases did not show aldosterone excess on both sides). Immunohistochemical evaluation of CYP11B2 was examined for 6 resected adrenal glands and all of them showed positive expression.

Association of demographic characteristics and endocrine parameters with systolic blood pressure

Among patients with overt hypercortisolism, we did not find a significant association of demographic characteristics and endocrine parameters with systolic blood pressure (Table 2).

However, among patients with subclinical hypercortisolism, we found that higher PAC at 8:00 AM were significantly associated with systolic blood pressure (adjusted coefficient [95% CI] = +0.59 [0.19 to 0.99], p-value=0.008). The results did not change when we used F after DST instead of F at 8:00 AM (Supplementary Table 2) (22).
Association of demographic characteristics and endocrine parameters with hypertension improvement after the adrenalectomy among patients with subclinical hypercortisolism

Among 33 patients with subclinical hypercortisolism and hypertension who underwent the adrenalectomy, we found that age and higher PAC were significantly associated with higher improvement rate of hypertension after the adrenalectomy (age, adjusted risk difference [95% CI] = +2.36% [1.08 to 3.64], p-value=0.001; PAC, adjusted risk difference [95% CI] = +1.45% [0.35 to 2.55], p-value=0.01; Table 3). The results did not change when we used F after DST instead of F at 8:00 AM (Supplementary Table 3) (22). Patients with the improvement of hypertension after the surgery showed significantly lower PAC 60 min during post-operative ACTH stimulation test than those without the improvement of hypertension (p-value=0.05), although F and PAC/F ratio were not significantly different between these two groups (Table 4). The association between lower PAC after post-operative ACTH stimulation and higher improvement rate of hypertension was also found in the multivariable regression analysis adjusting for baseline characteristics (adjusted risk difference [95% CI] = -1.08% [-1.92 to -0.25], p-value=0.01; Supplementary Table 4) (22).
Additional analyses

Decrease in PAC between before and after adrenalectomy was significantly associated with hypertension improvement after the adrenalectomy (Supplementary Table 5) (22). When we restricted samples to those without primary aldosteronism, PAC at baseline tended to be associated with systolic blood pressure but the 95%CI included the null (Supplementary Table 6) (22). Decrease in PAC after adrenalectomy was associated with hypertension improvement after the adrenalectomy while PAC at baseline was not associated with the outcome (Supplementary Table 7) (22). When we analyzed the entire sample (i.e., both overt and subclinical hypercortisolism), PAC at baseline was associated with systolic blood pressure at baseline (Supplementary Table 8) (22) and hypertension improvement after the adrenalectomy (Supplementary Table 9) (22). We also found the higher median value of PAC response to ACTH during adrenal venous sampling at the remained (i.e., not resected by the adrenalectomy) side of adrenal gland among patients who did not improve hypertension compared to those who improved hypertension after the surgery, but the difference was not statistically significant (Supplementary Table 10) (22).
Discussion

In this retrospective cohort study, we found that higher aldosterone levels were associated with higher systolic blood pressure among patients with possible autonomous cortisol secretion and without clinical signs of overt Cushing’s syndrome (i.e., subclinical hypercortisolism). In this group, higher aldosterone before the adrenalectomy was associated with the post-operative improvement of hypertension. Moreover, we found that patients with the postoperative improvement of hypertension showed lower aldosterone response to ACTH after the adrenalectomy compared to those without the improvement of hypertension.

Decrease in PAC after the adrenalectomy was associated with the improvement of hypertension even among patients with subclinical hypercortisolism who did not have primary aldosteronism at baseline, while baseline PAC was not associated with the outcome among them. We found no evidence that aldosterone is associated with systolic blood pressure among patients with overt hypercortisolism. These findings indicate that elevated aldosterone may contribute to the presence of hypertension and its improvement rate after the adrenalectomy for patients with subclinical hypercortisolism.

To the best of our knowledge, this is one of the first studies to assess the potential role of
aldosterone in hypertension among patients with overt and subclinical hypercortisolism,
during both pre- and post-operative phases. Since aldosterone- and cortisol-producing adenoma was reported in 1979,(23,24) several studies have assessed the cortisol production in aldosterone-producing adenoma clinically and histologically(8–10,25) and showed the correlation between the degree of glucocorticoid excess levels and metabolic markers including BMI, waist circumference, blood pressure, insulin resistance, and high-density lipoprotein.(12) Prior research suggested that aldosterone-producing adenoma might produce cortisol as well as aldosterone even when serum cortisol levels after DST is less than 1.8 µg/dL (50 nmol/L).(11) Although these studies have focused on cortisol synthesis among patients with aldosterone-producing adenoma, little is known about aldosterone synthesis among patients with cortisol-producing adenoma. Given that patients with hypercortisolism tend to have therapy-resistant hypertension and electrolyte disorders,(8) our findings may generate the hypothesis that aldosterone contributes to the incidence and severity of hypertension in patients with possible autonomous cortisol secretion that warrants further investigation.

There are several mechanisms by which cortisol excess leads to hypertension, such as
regulating endothelial nitric oxide synthase expression modulated by 11β-hydroxysteroid dehydrogenases (HSDs), activating the mineralocorticoid receptor (MR) and upregulating vascular endothelin-1. Moreover, hypercortisolism impairs the production of endothelial vasodilators including prostacyclin, prostaglandins, and kallikreins. Despite these potential mechanisms, the direct effect of cortisol may not be sufficient to explain hypertension in patients with hypercortisolism, particularly subclinical hypercortisolism, and the presence of cortisol and aldosterone co-producing adenoma indicates another potential pathway to induce hypertension through aldosterone excess. Aldosterone is a steroid hormone not only promoting sodium reabsorption and volume expansion but also activating the MR in the kidney and non-epithelial tissues (e.g., adipose tissue, heart, endothelial cells, and vascular smooth muscle cells, etc.). It also induces oxidative stress, inflammation, fibrosis, vascular tone, and endothelial dysfunction, and therefore, aldosterone excess could induce hypertension even when it is slightly elevated. A recent multi-ethnic study showed that aldosterone levels within the reference range were associated with subclinical atherosclerosis partially mediated through elevated blood pressure. These mechanisms support our results indicating the potential contribution of aldosterone to hypertension among patients with subclinical hypercortisolism.
This study had several limitations. First, we did not have information on the duration of cortisol excess, and therefore, the estimated effect of cortisol on hypertension in our study might have been underestimated. The duration of exposure to mild hypercortisolism may be one of the important drivers of cardiovascular and metabolic disorders including irreversible vasculature remodeling in patients with subclinical hypercortisolism. Second, we did not have the genetic information of adrenal tumors including aldosterone-producing adenoma. Given the heterogeneity of aldosterone responsiveness to ACTH and postoperative hypertension resolution rate across genetic mutations (e.g., KCNJ5, ATP1A1, ATP2B3, CACNA1D, and CTNNB1), such information might affect our findings. Third, due to the nature of an observational study, we cannot rule out the unmeasured confounding. Fourth, as aldosterone and cortisol levels were measured at a single point, we may have a risk of mismeasurement. Moreover, when evaluating aldosterone levels, we used dihydropyridine calcium channel blockers to control hypertension based on the clinical guideline of primary aldosteronism in Japan, which might lower serum aldosterone levels. Fifth, because the present study was conducted at a single-center, selection bias is inevitable. Given that primary aldosteronism—one of the major causes of secondary hypertension—has still been
underdiagnosed, partially due to insufficient recognition of clinical guidelines. Our findings may indicate the importance of considering aldosterone when evaluating patients with subclinical hypercortisolism accompanied by hypertension. However, we need to carefully interpret the observed “prevalence” in this study because individuals potentially having subclinical hypercortisolism were unlikely to come to our hospital which specializes the adrenal disorders, and thus the numbers do not reflect the prevalence in general population. A small number of resected adrenal glands with the evaluation of CYP11B2 expression in this study cohort also limit the prevalence estimation of primary aldosteronism. Finally, as we only followed up 1-year after the adrenalectomy, we could not evaluate the long-term resolution rate of hypertension. To overcome these limitations and generalize our findings, future molecular studies and multi-center longitudinal studies with sufficient individual datasets and longer follow-up are required.

In conclusion, plasma aldosterone concentrations were associated with systolic blood pressure and improvement rate of hypertension after the adrenalectomy among patients with subclinical hypercortisolism—possible autonomous cortisol secretion without clinical signs of overt Cushing’s syndrome. Our findings underscore the importance of considering
aldosterone when patients have an adrenal tumor with possible autonomous cortisol secretion complicated with hypertension. Future molecular and epidemiological studies are warranted to identify the potential role of aldosterone in hypertension among patients with subclinical hypercortisolism, clarify how often these patients also have primary aldosteronism, and examine the clinical effectiveness of the intervention targeting aldosterone for such patients.

**Figure Legend**

**Figure 1.** Enrollment and follow-up of the study population after the adrenalectomy.

\(^a\)The prevalence of patients with overt hypercortisolism and hypertension among this study population may be higher than general population, and therefore, needs to be carefully interpreted given that the study institute is one of the largest centers for adrenal diseases in Japan.

\(^b\)All patients in this category showed autonomous cortisol secretion (i.e. serum cortisol levels >5.0 µg/dL [138 nmol/L] after 1-mg dexamethasone suppression test.)

\(^c\)One case underwent adrenalectomy at another hospital, and therefore, no information available after the adrenalectomy.

\(^d\)The adrenalectomy was performed for 33 patients who were expected to improve their clinical symptoms and/or metabolic disorders including hypertension. This assessment was mainly based on autonomous cortisol secretion evaluated by 1-mg dexamethasone suppression test, complicated metabolic disorders, and autonomous aldosterone secretion evaluated by adrenal venous sampling for patients who showed positive for the screening and confirmatory tests of primary aldosteronism. Details in the assessment can be found in the method section or elsewhere. (18–20)

</tbody>
</table>

Abbreviations: eGFR, estimated glomerular filtration rate; ACTH, Adrenocorticotropic hormone; F, serum cortisol; PRA, plasma renin activity; PAC, plasma aldosterone concentration; DST, 1-mg dexamethasone suppression test.

\textsuperscript{a}ACTH and PRA were not included in the main model because they have strong correlation with F and PAC, respectively (i.e. multicollinearity). The results did not change when additionally adjusting for ACTH and PRA.

\textsuperscript{b}The results did not change when we replaced F at 8:00 AM with F after DST (Supplementary Table 2).

</table>

Abbreviations: eGFR, estimated glomerular filtration rate; ACTH, Adrenocorticotropic hormone; F, serum cortisol; PRA, plasma renin activity; PAC, plasma aldosterone concentration.

\(^a\) Analysis was not performed for patients with overt hypercortisolism because only 2/18 cases failed to show the improvement of hypertension after the adrenalectomy.

\(^b\) ACTH and PRA were not included in the main model because they have strong correlation with F and PAC, respectively (i.e. multicollinearity). The results did not change when additionally adjusting for ACTH and PRA.

\(^h\) The results did not change when we replaced F at 8:00 AM with F after DST (Supplementary Table 3).

Abbreviations: PAC, plasma aldosterone concentration; F, serum cortisol; ACTH, Adrenocorticotropic hormone.

Conversion to SI units: F, µg/dl × 27.6 for nmol/l; PAC, ng/dl × 27.7 for pmol/l.

\(^a\)Analysis was not performed for patients with overt hypercortisolism because only 2/18 cases failed to show the improvement of hypertension after the adrenalectomy.

\(^b\)The association was also observed after adjusting for baseline characteristics (e.g., age, sex, body mass index, systolic blood pressure, serum potassium, estimated glomerular filtration rate, tumor size) and F 60 min after ACTH stimulation a year after the adrenalectomy (Supplementary Table 4).
