## ABSTRACT

Direct oxygen partial pressure (pO<sub>2</sub>) readings in cancers of the cervix and in the normal cervix of nulliparous or parous women were obtained using a computerized pO<sub>2</sub> histography system. The oxygenation status of the tumors was evaluated as a function of clinical staging and histological grading. pO<sub>2</sub> measurements were performed with a customized electrode system in conscious pre- and postmenopausal, untreated patients with well-defined arterial blood gas status.

With this technique, pO<sub>2</sub> measurements in the normal cervix of nulliparous women resulted in oxygenation patterns which were characteristic for normal, adequately supplied tissues (median pO<sub>2</sub>, 48 mm Hg) with approximately 1% of the pO<sub>2</sub> values grouped between zero and 2.5 mm Hg, *i.e.*, in a range with less than half-maximum radiosensitivity. As a rule, the mean (and median) pO<sub>2</sub> values were distinctly lower in the normal cervix of parous women (most probably due to scar formation following vaginal delivery) and in malignancies. In the normal cervix of parous women the median pO<sub>2</sub> value was 13 mm Hg (with approximately 14% of the pO<sub>2</sub> readings in the lowest class), 14 mm Hg in International Federation of Gynecologists and Obstetricians I/II tumors (2% of the readings in the lowest pO<sub>2</sub> class), and 11 mm Hg in International Federation of Gynecologists and Obstetricians III/IV cancers (1% of the pO<sub>2</sub> data in the lowest class). To date, 5 of 18 cervical cancers exhibited pO<sub>2</sub> values between zero and 2.5 mm Hg. The oxygenation pattern in cervical cancers and the occurrence of hypoxia and/or anoxia did not correlate with either the clinical stages and histological grades or with a series of clinically relevant parameters (*e.g.*, tumor size). No significant differences were found between pre- and postmenopausal tumors, between squamous cell carcinomas and adenocarcinomas, and between endophytic or exophytic tumors.

From these studies there is clear indication that the oxygenation status of individual tumors cannot be predicted on the basis of staging and/or grading, predominantly because of the pronounced tumor-to-tumor variabilities. Evaluation of the tissue oxygenation of individual tumors is thus mandatory to prove that tumor oxygenation can predict the overall prognosis and/or treatment outcome.

## INTRODUCTION

It has recently been shown that the oxygenation pattern in human breast cancers and the occurrence of hypoxia and/or anoxia does not correlate with either the pathological stages or the histological grades of the tumors investigated (1). In earlier studies Kolstad (2, 3) demonstrated a correlation between the mean and lowest observed tissue oxygen tensions and the stage of disease in superficial regions of cervical cancers. Furthermore, Kolstad's data suggested that an association existed between large intercapillary distances, local recurrence and clinical staging. The latter finding has been confirmed by Awwad *et al.* (4) and by other investigations emphasizing the predictive value of the vascular density (which may reflect the tumor oxygenation) for survival after radiotherapy (5-8).

Thus far, pO<sub>2</sub> values determined in cervical cancers cannot be considered correct on an absolute scale (3, 9-12). Artifacts

due to large electrodes and thus tissue compression (11), problems with the calibration of the sensor (10), and the use of bare electrodes (9, 10, 12) are obvious in the earlier studies. Bare sensors monitor O<sub>2</sub> concentrations instead of O<sub>2</sub> partial pressures (O<sub>2</sub> tensions). For the evaluation of oxygen tension (pO<sub>2</sub>) distribution in tissues, membrane-covered O<sub>2</sub> sensors are required (13). A direct conversion of O<sub>2</sub> concentrations (cO<sub>2</sub>) into pO<sub>2</sub> values according to the Henry-Dalton law (cO<sub>2</sub> =  $\alpha \cdot pO_2$ ) is not possible, since the O<sub>2</sub> solubility coefficient ( $\alpha$ ) is anisotropic in tissues (14). In addition, the validity of the O<sub>2</sub> data reported earlier is limited due to measurements in the tumor periphery only (3, 9-12) and due to a selection of patients with stage II malignancies (9-12). Reports on the oxygenation pattern of advanced malignancies are lacking. Furthermore, monitoring of the arterial blood gas status, which is mandatory for the evaluation of tissue oxygenation patterns, has not been performed in the earlier studies.

Reliable pO<sub>2</sub> readings in normal and malignant tissues are now possible using a novel, commercially available technique (computerized pO<sub>2</sub> histography) which allows for the systematic evaluation of the tissue oxygenation status. The measuring procedure uses a computerized O<sub>2</sub> sensor movement, minimizes compression artifacts, and has been shown to represent a valid method for analysis of tissue oxygenation patterns (for a recent description of this technique see Ref. 1).

Using this novel technique, the objective of this study was to investigate the oxygenation pattern in primary cancers of the uterine cervix in conscious patients, placing emphasis on a well defined arterial blood gas status and on the evaluation of the pO<sub>2</sub> distribution as a function of clinical staging and histological grading. Cervical carcinomas were selected as a tumor entity because radiation is a major treatment modality for this disease and tumor hypoxia is regarded an important factor for radioresistance in these tumors. In addition, accessibility of these malignancies allows systematic studies under clinical conditions.

The key questions were as follows: Do the pO<sub>2</sub> data obtained with this method match with earlier results suggesting low mean O<sub>2</sub> tensions or concentrations in cervical cancers? What are the absolute pO<sub>2</sub> values in cervical cancers as a function of clinical staging and histological grading? Are there differences in the oxygenation between squamous cell carcinomas and adenocarcinomas? Other key issues of this investigation were the comparison of the oxygenation pattern in normal cervical tissue and in malignancies, of the pO<sub>2</sub> distribution in the normal cervix of *para versus* nullipara, and the evaluation of O<sub>2</sub> patterns in central *versus* superficial tumor regions.

## MATERIALS AND METHODS

**Patients.** As part of a prospective study on untreated patients with cancer of the uterine cervix which aims to assess the relevance of pO<sub>2</sub> measurements in individual tumors for local control after therapy, we have evaluated intratumor pO<sub>2</sub> measurements in 7 pre- and 11 postmenopausal conscious patients (age, 27-80 years) entering the study. Fifteen women presented with histologically confirmed squamous cell

carcinomas; 3 patients presented with adenocarcinomas. These patients were referred to the Department of Obstetrics and Gynecology, University of Mainz (Germany), for either surgical or irradiation treatment. None of the tumors had been treated previously. The relevant patient characteristics and tumor data are summarized in Table 1. Clinical staging according to the FIGO<sup>2</sup> classification (15) was performed independently by two experienced staff members. In case of disagreement with respect to parametrial tumor invasion, the patient was examined by a third staff member. For histological grading Broder's system was applied (16).

Cervical and/or cervical tumor diameters were measured during speculum examination. For determining the cervical (tumor) length in tumor patients, X-ray hystero-graphy was carried out with a surgical needle introduced into the outer surface of the portio. In addition, cervical (tumor) diameters were calculated from magnetic resonance imaging of the pelvis in coronal and sagittal planes. In healthy control subjects ( $n = 14$ ; normal arterial blood gas status) cervical diameters were also measured during speculum investigation. Cervical lengths in the controls were determined by vaginosonography. Characteristics of control subjects are given in Table 2.

All patients and control subjects were fully informed about the experimental nature of the present investigation, gave consent without reservation, and experienced the absolute minimum of discomfort. In cancer patients, the tissue containing the electrode tracks was subsequently completely removed by ablative surgery or included into the target volume in the case of irradiation.

Measurements of Tissue Oxygen Tension Values with Needle Electrodes. For the measurement of tissue oxygen tension ( $pO_2$ ) values, sterile polarographic needle electrodes with stainless steel shafts (of the hypodermic needle type) were used ( $pO_2$  histography, model KIMOC-6650; Eppendorf, Hamburg, Germany). The probes had a shaft diameter of 300  $\mu m$ . The sharply ground tips of the probes contained a membranized polarographic, recessed microcathode in the form of a gold wire 12  $\mu m$  in diameter. Technical data for the needle electrodes, and a detailed description of the calibration procedure and of the data display have been given earlier (1). For the  $pO_2$  measurements in uterine cervixes and cervical cancers, all patients and control subjects were placed in the lithotomy position. This positioning was consistently used throughout all measurements because changes of the leg position yield alterations in the  $pO_2$  distribution in the pelvic organs (e.g.,  $pO_2$  values in the normal cervix of patients in the supine position with the lower legs below heart level are significantly lower than in patients placed in the lithotomy position<sup>3</sup>). Self-retracting specula were inserted into the vagina. In control subjects, the portio was positioned by means of a tenaculum in such a way that  $pO_2$  measurements could be performed parallel to the cervical canal. In a pilot study, it was found that this positioning of the portio had no significant influence on the oxygenation pattern of the cervix. In cancer patients,  $pO_2$  measurements were performed without positioning of the tumorous cervix due to the lack of the normal topography and the fixation of the tumor mass in the pelvis. The reference electrode was placed on the patient's left thigh.

In general, 2 defined electrode tracks were evaluated in each tumor, at the 12 and 6 o'clock positions, and 5 to 10 mm distal to the cervical canal or at the tumor margin. In some patients additional measurements were performed at the 2, 4, 8, and 10 o'clock positions. A plastic trocar (outer diameter, 0.8 mm) equipped with a hypodermic needle was advanced to an initial depth of approximately 2 mm. The hypodermic needle was then removed and the trocar was cut at 7 mm length so that it protruded 5 mm out of the tissue surface. The  $O_2$ -sensitive electrode was guided through the trocar for tissue  $pO_2$  measurements.  $pO_2$  recordings in both peripheral and central tumor areas were performed in all electrode tracks chosen. This was confirmed by inspections of giant sections of surgical specimens in those patients undergoing radical hysterectomy.

The electrode was automatically moved through the tissue parallel to the cervical canal in preset steps of 1 mm. Each rapid forward

<sup>a</sup> BP, arterial blood pressure; HbO<sub>2</sub>, arterial oxyhemoglobin saturation; s.c.c., squamous cell carcinoma; ad.ca., adenocarcinoma; n.d., not determined.

movement was immediately followed by a backward step of 30% of the forward motion in order to minimize compression effects caused by the forward motion of the O<sub>2</sub>-sensitive needle electrode. This motion pattern led to an effective forward step length of maximally 0.7 mm. Depending on the tumor size, a sufficient number, *n*, of pO<sub>2</sub> readings (*n* > 50) were obtained in order to present the data by means of pO<sub>2</sub> frequency distributions (pO<sub>2</sub> histograms) which can reflect the oxygenation pattern of individual tumors.

The total length of the measuring canal corresponded to the length of the cervix or to the length of the cervical tumor if the latter did not exceed 40 mm. Otherwise a measuring length equal to one-half of the sagittal cervix/tumor diameter was used. At the end of the measurement the pO<sub>2</sub> probe was automatically removed from the tissue. In cancer patients the pO<sub>2</sub> measurements were carried out immediately before initiation of therapy. All measurements were conducted on conscious women not undergoing any cancer treatment.

**Monitoring of Relevant Systemic Parameters.** In order to guarantee that tissue pO<sub>2</sub> measurements were exclusively performed during arterial normoxemia, basic cardiovascular parameters (e.g., heart rate, arterial blood pressure) and factors determining the arterial O<sub>2</sub> concentration (e.g., hemoglobin concentration, hematocrit, arterial oxyhemoglobin saturation) were monitored during the measuring procedures (1).

**Statistical Analysis.** Using an on-line computing system, pO<sub>2</sub> histograms (i.e., pO<sub>2</sub> frequency distributions) were obtained with a class width of 2.5 mm Hg. The distribution of the measured pO<sub>2</sub> values was characterized by the mean pO<sub>2</sub>, the median pO<sub>2</sub>, and the 10 and 90 percentile values. For statistical evaluation of possible differences between groups the Mann-Whitney-Wilcoxon *U* test was used, if not stated otherwise.

**RESULTS**

Using the computerized pO<sub>2</sub> histography system, pO<sub>2</sub> values were recorded in the normal cervix of nullipara and para and in cancers of the uterine cervix of different clinical stages and histological grades. As a rule, the mean (and median) pO<sub>2</sub> values were distinctly lower in the malignancies and in the normal cervix of parous women than in the normal cervix of nulliparous women (see Figs. 1 and 2). The histograms for parous and nulliparous, healthy subjects were significantly different (*P* < 0.02). No differences in the oxygenation pattern of the normal uterine cervix were found between smokers and nonsmokers or users and nonusers of oral contraceptives.

In cancer patients, no differences in the pO<sub>2</sub> distribution were obvious between adenocarcinomas and squamous cell carcinomas; among endophytic (*n* = 4), exophytic (*n* = 8), and ulcerated tumors (*n* = 6); between para (*n* = 15) and nullipara (*n* = 3); or between pre- and postmenopausal patients. Pooled pO<sub>2</sub> histograms in cancer patients were similar to those obtained in the normal cervix of parous women. Thus far, 5 of 18 cervical cancers exhibited pO<sub>2</sub> values between zero and 2.5 mm Hg, i.e., tissue areas with less than half-maximum radiosensitivity. One of 7 normal cervixes in nulliparas and 3 of 7 cervixes in paras exhibited pO<sub>2</sub> values between zero and 2.5 mm Hg.

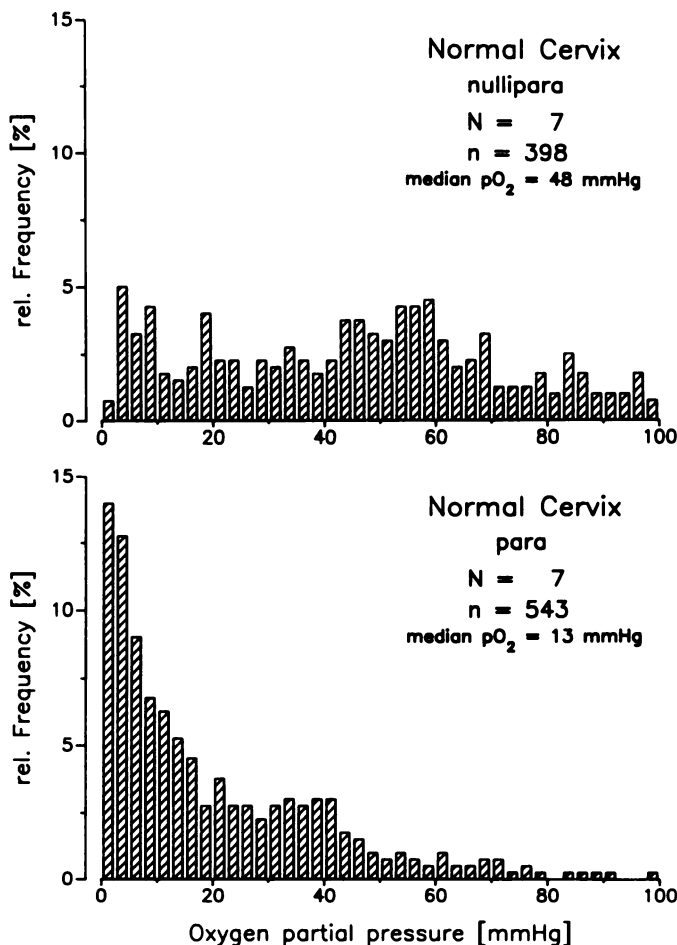

Fig. 1. Frequency distributions of measured oxygen partial pressures (pO<sub>2</sub> histograms) for normal cervix of nulliparous (top) and parous (bottom) women. N, number of patients; n, number of pO<sub>2</sub> measurements.

Pooled data for all cervical cancers of clinical stages FIGO I and II are presented in Fig. 2, top, whereas the respective pO<sub>2</sub> histogram for malignancies of stages FIGO III and IV are shown in Fig. 2, bottom. This compilation provides clear evidence that there are no statistically significant differences between the two groups (median pO<sub>2</sub> in FIGO I/II tumors, 14 mm Hg; median pO<sub>2</sub> in FIGO III/IV tumors, 11 mm Hg). This implies that the clinical stages of the cervical cancers investigated thus far cannot be the paramount factor determining tumor tissue oxygenation. Surprisingly, the number of pO<sub>2</sub> readings in the "hypoxic" class (0–2.5 mm Hg) is lower in FIGO III/IV than in FIGO I/II tumors.

Based on the oxygenation pattern of the malignancies investigated there is substantial experimental evidence that the occurrence of radiobiological hypoxia does not correlate with the

clinical stage and the histological grade and other clinically relevant parameters. Correlations between staging or grading and the number of  $pO_2$  readings on zero level, the mean or median  $pO_2$ , and the 10% or 90% percentiles could not be detected.

There is marked tumor-to-tumor variability, even if tumors of the same clinical stage (FIGO II), grade (G2), and histology (squamous cell carcinomas) are compared (see Fig. 3). In the case presented in Fig. 3, *top*, all measured  $pO_2$  values are higher than 18 mm Hg and thus indicative of a relative radiosensitivity  $>2.4$  (17). In contrast, oxygenation of the cervical cancer shown in Fig. 3, *bottom*, contains a significant volume of tissue (at least 20%) with less than half-maximum radiosensitivity.

As a result of intratumor heterogeneities, a certain number of  $pO_2$  measurements in different electrode tracks through a tumor is required in order to obtain sufficient information on the oxygenation status of an individual tumor. In 5 patients we compared the  $pO_2$  histograms obtained from 2 "standard" electrode tracks (at 6 and 12 o'clock positions) with those evaluated from multiple tracks (up to 10 additional electrode passages). No significant differences were found when  $>40$   $pO_2$  values were recorded per track. If the lowest  $pO_2$  class (0–2.5 mm Hg) is considered, there were no differences when multiple *versus* "standard" electrode tracks were compared. Additionally, similar  $pO_2$  histograms were usually obtained when the same tumor region was measured repeatedly during a 1-day observation period using different  $O_2$ -sensitive electrodes.

In the cervical cancers studied, high and low  $pO_2$  values were randomly distributed in both tumor periphery and center.

## DISCUSSION

Oxygen tension measurements were performed in the normal cervix and in cervical cancers of conscious women using a novel polarographic device capable of reliable tissue  $pO_2$  determinations. In the normal cervix of nullipara, during controlled arterial blood gas status, a  $pO_2$  distribution was found similar to that of most normal tissues (1, 17). In contrast, a left-shifted  $pO_2$  histogram with a reduction of median oxygen levels and an asymmetry toward lower  $pO_2$  values was observed in the cervix of para. The existence of tissue areas with less than half-maximum radiosensitivity (approximately 13% of the  $pO_2$  readings) is a finding which has not been addressed previously and, in addition, had not been expected by earlier investigators. This pronounced left shift of the  $pO_2$  histogram most probably is due to the scar formation in the cervix after vaginal delivery(ies). The biological and clinical significance of the lower oxygenation status of parous women is not clear at present and deserves further investigation.

When comparing the tissue oxygenation of cervical cancers (FIGO I-IV) with that found in the normal cervix of parous women, a clear-cut difference was not observed. In both instances, left-shifted  $pO_2$  distributions were found with a higher percentage of  $pO_2$  readings in lowest  $pO_2$  class (0–2.5 mm Hg) in the normal cervix of parous women.

<sup>a</sup> Estimated mean (range); measurement with bare electrodes in superficial tissue regions.

<sup>b</sup> Median pO<sub>2</sub> value.

When stage II and III tumors are considered, almost identical median pO<sub>2</sub> values compared with the data evaluated for normal cervix of para were found (see Table 3). Only when the tumor data are related to the median pO<sub>2</sub> value of the normal cervix of nullipara is a ratio of approximately 3.4 for stage II tumors obtained. This latter ratio is distinctly higher than that reported earlier for stage II cervical cancers [2.2 (2) and 2.5 (10)]. This difference may partly be due to the fact that in the latter studies no distinction was made between nulliparous and parous patients.

As was the case with breast cancers (1), the oxygenation pattern and the occurrence of low pO<sub>2</sub> readings did not correlate with either the clinical stages and histological grades or with the tumor histology (squamous cell carcinomas *versus* adenocarcinomas), the location of the pO<sub>2</sub> measurements (center *versus* periphery), and a series of other clinically relevant factors. Again, from these clinical studies there is clear indication that the oxygenation status of individual tumors before therapy cannot be predicted solely on the basis of staging and/or grading. This is mostly due to pronounced tumor-to-tumor (and intratumor) pO<sub>2</sub> variabilities. Evaluation of the tissue oxygenation of individual tumors is thus mandatory to prove that tumor oxygenation can predict the overall prognosis and/or treatment outcome.

When comparing the oxygenation pattern of breast cancers (pathological stages T1-4) with that of cervical cancers (clinical stages FIGO I-IV), one striking difference has to be mentioned. Whereas the number of pO<sub>2</sub> readings in the lowest class is almost identical in the cervix and breast cancers investigated (2 *versus* 3%), the two pO<sub>2</sub> histograms are significantly different ( $P < 0.005$ ), with a better oxygenation in the breast cancers (White test) (18, 19). This may be at least partially due to the larger size of the cervical cancers investigated (mean maximum diameter in cervical cancers, 6.1 cm *versus* 3.1 cm in breast cancers;  $P < 0.0001$ ). However, when the cervix and breast

cancers are considered as separate groups there is thus far no indication that a correlation exists between median pO<sub>2</sub> values and tumor sizes.
