Aims

Although aberrant Ca$^{2+}$ release (i.e. Ca$^{2+}$ ‘leak’) from the sarcoplasmic reticulum (SR) through cardiac ryanodine receptors (RyR2) is linked to heart failure (HF), it remains unknown whether and under what conditions SR-derived Ca$^{2+}$ can actually cause HF. We tested the hypothesis that combining dysregulated RyR2 function with facilitated Ca$^{2+}$ uptake into SR will exacerbate abnormal SR Ca$^{2+}$ release and induce HF. We also examined the mechanisms for these alterations.

Methods and results

We crossbred mice deficient in expression of cardiac calsequestrin (CASQ2) with mice overexpressing the skeletal muscle isoform of SR Ca$^{2+}$-ATPase (SERCA1a). The new double-mutant strains displayed early mortality, congestive HF with left ventricular dilated hypertrophy, and decreased ejection fraction. Intact right ventricular muscle preparations from double-mutant mice preserved normal systolic contractile force but were susceptible to spontaneous contractions. Double-mutant cardiomyocytes while preserving normal amplitude of systolic Ca$^{2+}$ transients displayed marked disturbances in diastolic Ca$^{2+}$ handling in the form of multiple, periodic Ca$^{2+}$ waves and wavelets. Dysregulated myocyte Ca$^{2+}$ handling and structural and functional cardiac pathology in double-mutant mice were associated with increased rate of apoptotic cell death. Qualitatively similar results were obtained in a hybrid strain created by crossing CASQ2 knockout mice with mice deficient in phospholamban.

Conclusion

We demonstrate that enhanced SR Ca$^{2+}$ uptake combined with dysregulated RyR2s results in sustained diastolic Ca$^{2+}$ release causing apoptosis, dilated cardiomyopathy, and early mortality. Our data also suggest that up-regulation of SERCA activity must be advocated with caution as a therapy for HF in the context of abnormal RyR2 function.

Calsequestrin • SERCA • CPVT • Heart failure • Apoptosis

1. Introduction

Abnormal intracellular calcium (Ca$^{2+}$) handling, and in particular, dysregulated Ca$^{2+}$ release from the sarcoplasmic reticulum (SR), has been implicated in a range of cardiac diseases, including arrhythmias and systolic heart failure (HF). In cardiac muscle, Ca$^{2+}$-induced Ca$^{2+}$ release (CICR) from the SR via ryanodine receptor channels (RyR2s) during the action potential results in systolic contraction. The SR Ca$^{2+}$-binding protein calsequestrin (CASQ2) plays an important role in the regulation of SR Ca$^{2+}$ release by both buffering Ca$^{2+}$...
in the SR and facilitating RyR2 closure during the diastolic phase.\textsuperscript{2} Re-uptake of Ca\textsuperscript{2+} by the SR Ca\textsuperscript{2+} ATPase (SERCA2a) pump initiates diastolic relaxation.

Mutations in RyR2 and CASQ2 have been linked to catecholaminergic polymorphic ventricular tachycardia (CPVT), a cardiac rhythm disorder characterized by episodes of ventricular tachycardia following exercise or infusion of catecholamines in patients with otherwise functionally and anatomically normal hearts.\textsuperscript{7} At myocyte level, the mutations have been shown to destabilize RyR2 activity thus causing premature Ca\textsuperscript{2+} release in the form of spontaneous Ca\textsuperscript{2+} waves, followed by oscillations of membrane potential, known as delayed afterdepolarizations, and extra-systolic action potentials.\textsuperscript{4,5} However, the mechanisms underlying the adverse effects of adrenergic stimulation in CPVT remain to be fully elucidated.

It has also been suggested that excessive diastolic SR Ca\textsuperscript{2+} release causes HF,\textsuperscript{6–8} a disease state determined by compromised systolic and/or diastolic myocardial function and hypertrophy. SR-derived Ca\textsuperscript{2+} could also activate Ca\textsuperscript{2+}-dependent signalling cascades resulting in pathological remodelling and/or myocyte death, thus contributing to HF development.\textsuperscript{9,10} Although dysregulated RyR2 activity and diastolic SR Ca\textsuperscript{2+} release are characteristic features of advanced HF in both humans and animal models,\textsuperscript{6–8,11,12} it remains unclear whether abnormal RyR2-mediated Ca\textsuperscript{2+} signalling plays a causal role in HF development. Indeed, while >100 mutations in RyR2 and 12 in CASQ2 have been reported in human families,\textsuperscript{6–8} HF is so complex that it is likely that many different genetic abnormalities contribute to HF development. Indeed, while mutations in RyR2 and CASQ2 have been linked to catecholaminergic CPVT,\textsuperscript{6–8} the mechanisms underlying the adverse effects of adrenergic stimulation in CPVT remain to be fully elucidated.

For details regarding methods, refer to the Supplementary material online, Methods.

2. Methods

2.1 Generation of mouse models

Double-mutant mice for CASQ2 and SERCA1a were generated by breeding two previously described mouse models, the SERCA1a TG mouse\textsuperscript{13} with the CASQ2 KO mouse.\textsuperscript{16} WT, TG, KO, CASQ2 heterozygous expressing SERCA1a (HETxTG), and KO expressing SERCA1a (KOxTG) mice were used for the study. Double knockout mice (DKO) for CASQ2 and PLB were created by breeding KO mice for CASQ2 (Ko) with PLB.KO mice.\textsuperscript{14} Male, age- and littermate-matched control, and experimental animals were used for all the described studies. This investigation conforms to the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health (NIH Publication No.85-23, revised 1996) and the National Research Council Guide for the Care and Use of Laboratory Animals: 8th Edition published by The National Academies Press, 2011, Washington, DC. All the animal experimental protocols were approved by the Institutional Animal Care and Use Committee of The Ohio State University.

2.2 Echocardiography and electrocardiographic recordings

Echocardiographic (ECG) examination was performed to assess systolic and diastolic function in lightly anaesthetized mice (1.5% isoflurane), using the Vevo 2100 echocardiograph system (with a 30 MHz probe), following standard techniques, as previously described. Continuous ECG recordings were obtained from mice anaesthetized with isoflurane, at minimum effective concentration (1–1.5%) before and after catecholaminergic challenge [isoproterenol (ISO) (1.5 mg/kg ip)], as previously described. Anaesthesia of mice was considered sufficient when the paw pinch test was negative.

2.3 Western blotting

Quantitative immunoblotting was done as previously reported.

2.4 Evaluation of apoptosis using TUNEL staining

Paraformaldehyde-fixed whole heart sections were stained for TUNEL-positive nuclei, using a kit (ROCHE) according to the manufacturer’s instructions.

2.5 Cardiac muscle preparation

Mice were administered heparin [40 μL, heparin sodium 10 000 U/mL, APP Pharmaceuticals, LLC, Schaumburg, IL, USA (ip)] 10 min before receiving anaesthesia (pentobarbital sodium 70 mg/kg, ip, Lundbeck Inc., Deerfield, IL, USA). Anaesthesia of mice was considered sufficient when the paw pinch test was negative. Thin, uniform, non-branched trabeculae, or small papillary muscles from the right ventricle were mounted between a force transducer and a micromanipulator and stretched to an optimal length as previously described. All experiments were performed at 37°C. The developed tension was recorded with the LabView software and normalized to the cross-sectional area of the muscle.

2.6 Mouse cardiomyocyte isolation and confocal Ca\textsuperscript{2+} measurements

Ventricular myocytes were isolated from mouse hearts by Collagenase (Worthington) digestion as previously reported. Confocal Ca\textsuperscript{2+} imaging was performed using a Nikon A1 laser scanning confocal microscope equipped with a ×60 1.4 NA oil objective.

2.7 Statistical methods

Data are presented as mean ± SEM and tested with Student’s two-tailed t-test. Kaplan–Meier survival curves were plotted and tested with the SPSS software [Log Rank (Mantel-Cox) test]. ECG data were analysed by cross tabulations with χ² and one-way analyses of variance were performed, as appropriate. P-values <0.05 were considered significant.

3. Results

3.1 Mice deficient in CASQ2 and expressing SERCA1a display premature mortality with signs of cardiac enlargement and pulmonary congestion

Double-mutant mice for SERCA1a expression with either partial (HETxTG) or complete ablation of CASQ2 (KOxTG) died early.
100% mortality rates were 66 days (37 ± 2.6) and 226 days (115 ± 3.4) in the KOxTG and HETxTG mice, respectively (Figure 1A). No animals died in the WT, KO, and TG groups during the study period (>15 months). Post-mortem examinations of the KOxTG and HETxTG animals revealed cardiac enlargement and wall thinning (Figure 1E) with evidence of lung oedema and significantly increased lung weight-to-body weight ratios [WT: 5.27 ± 0.16; HETxTG: 11.04 ± 1.50, (P < 0.05); KO: 5 ± 0.02; and KOxTG: 10.75 ± 0.15, (P < 0.05) mg/g] compared with the KO and the WT groups, respectively (Figure 1B). The heart-to-body weight ratios were increased approximately two-fold in the HETxTG and the KOxTG [WT: 5.00 ± 0.12, HETxTG: 10.00 ± 0.20, (P < 0.05), KO: 5.00 ± 0.19, KOxTG: 8.91 ± 0.90 (P < 0.05) (mg/g)] mice compared with the age-matched WT and KO mice, respectively (Figure 1C).

**Figure 1** Premature mortality and pathological structural remodelling of the myocardium in the HETxTG and the KOxTG mice. (A) Kaplan–Meier survival plot. (B) Lung weight/body weight ratio. (C) Heart weight/body weight ratio. (D) Average cardiomyocyte cross-sectional area. (E) Representative Haematoxylin and Eosin stained paraffin sections show wall thinning and dilatation in the HETxTG (3.5 months old) and the KOxTG (30 days old) hearts compared with the age-matched WT and KO hearts (×10 magnification) (n = 5). (F) Vacuolation and megakaryosis in the HETxTG mice hearts (indicated by black arrows) and mineralization in the KOxTG hearts (indicated by blue arrows) (n = 5). (G) Fibrosis demonstrated by Masson Tri-chrome staining in the HETxTG and the KOxTG hearts (n = 5). (H) WGA staining of cell membranes in the HETxTG and the KOxTG hearts (n = 3). All values reported as mean ± SEM (*P < 0.05); sample sizes are indicated within the respective column (HET, heterozygous and KO, knock-out for CASQ2; TG, expresses SERCA1a transgene).
3.2 CASQ2-deficient mice overexpressing SERCA1a display dilated cardiac hypertrophy and contractile dysfunction

We further examined the structural and functional alterations in the double-mutant hearts using histological and haemodynamic assays. Haematoxylin and Eosin staining revealed widespread signs of degenerative changes in HETxTG and KOxTG cardiomyocytes including loss of striations, vacuolation, megakaryosis, and mineralization (Figure 1F). Additionally, Masson trichrome staining exposed focal areas of moderate interstitial fibrosis in sections from double-mutant hearts (Figure 1G) compared with the normal histology from the age-matched WT and KO cardiac sections. No significant differences in the cardiomyocyte size were observed in the TG (199 ± 1 μm²) and the KO (153 ± 4 μm²) hearts compared with the WT (138 ± 3 μm²) hearts. A significant increase in the myocyte size was detected in both the HETxTG (599 ± 20 μm²; P < 0.05) and the KOxTG (328 ± 10 μm²; P < 0.05) hearts compared with the age-matched WT and KO hearts, respectively (Figure 1D and H). In both genotypes, myocyte hypertrophy was not regionally restricted but observed consistently both transmurally and from the apex to the base of the ventricles.

Left ventricular (LV) enlargement and impaired cardiac function in mice combining CASQ2 ablation and SERCA1a expression were indicated by echocardiography (Figure 2A). The end-diastolic diameter of the left ventricle was significantly enlarged (3.54 ± 0.13 vs. 4.48 ± 0.2 mm, P < 0.05) and LV posterior wall dimension diastole (LVPWD) was decreased (0.95 ± 0.06 vs. 0.73 ± 0.05 mm, P < 0.05) in the WT vs. the HETxTG mice (see Supplementary material online, Table S1). Ejection fraction was reduced in double-mutant mice (Figure 2B). Taken together, these results suggest that double-mutant mice developed dilated cardiomyopathy.

3.3 Catecholamine-induced arrhythmias are exacerbated in CASQ2-deficient mice overexpressing SERCA1a

ECG traces were recorded from lightly anaesthetized mice before and after catecholaminergic challenge with ISO. Continuous ECG monitoring showed a nearly normal sinus rhythm at the baseline, except for a relatively few cases of premature ventricular complexes (PVCs) in the HETxTG group (see Supplementary material online, Figure S1A). Following the ISO challenge, both the HETxTG and the KOxTG groups showed a marked increase in the incidence of arrhythmias (see Supplementary material online, Figure S1B). Importantly, while the HETxTG mice primarily displayed simple ventricular arrhythmias (consisting of PVCs and fusion beats), the KOxTG mice also developed complex ventricular arrhythmias, including ventricular tachycardia (see Supplementary material online, Figure S1B–D).

**Figure 2** LV contractile function is decreased in the HETxTG and the KOxTG mice. (A) Representative images of M-mode echocardiograms. IVS, interventricular septum; LVPW, left ventricular posterior wall; RV, right ventricle; LVID, left ventricular internal diameter. (B) Mean ± SEM of LV ejection fraction (%); *P < 0.05. (HET, heterozygous and KO, knockout for CASQ2; TG, expresses SERCA1a transgene).
3.4 Intrinsic cardiac muscle contractility is preserved in CASQ2-deficient mice expressing SERCA1a

To determine whether the impaired LV haemodynamic performance in double-mutant mice is associated with weakening of intrinsic myocardial contractility, we performed contractile force measurements in ventricular papillary muscles paced at 4 Hz at 37°C. As shown in Figure 3, the systolic contractile force in the HETxTG muscles, rather than being weaker, tended to be stronger than in the age-matched WT muscles. Similarly, the KOxTG muscles contracted more strongly than the KO muscles. Of note, both HETxTG and KOxTG muscles showed occasional spontaneous diastolic contractions, which were rarely observed in the WT, TG, and the KO muscles (Figure 3A, bottom panels; Figure 3C). Exposure to ISO (0.3–1 μM) led to regular diastolic contractions in all the three types of CASQ2-deficient muscles (HETxTG, KOxTG, and KO) but not in the WT or the TG muscles. Thus, in vivo cardiac contractile dysfunction in mice combining CASQ2 deficiency with up-regulated SR Ca<sup>2+</sup> uptake develops in the absence of decreased intrinsic cardiac muscle contractility. Consistent with the in vivo ECG studies, muscles from the double-mutant mice showed an enhanced propensity towards diastolic, spontaneous contractile activity that was further exacerbated by ISO.

3.5 Cardiomyocytes from CASQ2-deficient mice expressing SERCA1a display enhanced diastolic SR Ca<sup>2+</sup> release

To directly examine the effects of combining CASQ2 ablation with expression of SERCA1a on myocyte Ca<sup>2+</sup> handling, we performed intracellular confocal Ca<sup>2+</sup> imaging and Ca<sup>2+</sup> current measurements in isolated cardiomyocytes from double-mutant mice and the three control groups (i.e. WT, KO, and TG). As expected, expressing SERCA1a in the background of deficient CASQ2 expression resulted in a marked increase in diastolic Ca<sup>2+</sup> release that manifested in
repetitive multiple propagating wave- or wavelet-like signals in both KOxTG and HETxTG myocytes (Figure 4A and F). All the other groups, including TG and KO myocytes, exhibited such spontaneous releases at much lower rates under the same experimental conditions (Figure 4B). In addition, average diastolic Ca\(^{2+}\), as a total measure of diastolic release, was significantly increased in the double-mutant myocytes compared with the other groups (see Supplementary material online, Figure S2). Of note, the amplitude of systolic Ca\(^{2+}\) transients and SR Ca\(^{2+}\) content in the double-mutant myocytes were either higher or similar to those in the WT but lower than those in the TG myocytes. The reduced SR Ca\(^{2+}\) content of the double-mutant myocytes relative to the SERCA1a myocytes is evidently due to the increased diastolic release in the double-mutant myocytes which would be expected to deplete the SR Ca\(^{2+}\) store (Figure 4C–E). Ca\(^{2+}\) currents measured in separate experiments in the double-mutant myocytes were not significantly different in amplitude compared with the WT and the other groups (see Supplementary material online, Figure S3). Additionally, key Ca\(^{2+}\)-handling proteins, including SERCA1a, SERCA2a, CASQ2, RyR2, and PLB, were assessed by western blotting in the hearts from different groups (see Supplementary material online, Figure S4). SERCA1a levels were similar in all the groups overexpressing this protein. Consistent with previous results, endogenous SERCA2a\(^{13}\) and RyR2\(^{17}\) were decreased in the hearts overexpressing SERCA1a.

Figure 4 Cardiomyocytes from CASQ2-deficient mice expressing SERCA1a display enhanced diastolic SR Ca\(^{2+}\) release. (A) Representative line-scan images and temporal profiles of Fluo-3 fluorescence recorded in the WT and the KOxTG myocytes stimulated at 0.5 Hz. Top: field-stimulation protocol. Timing of electrical stimulations is indicated by upward deflections. (B) Distributions of diastolic Ca\(^{2+}\) wave (DCW)/cycle (KOxTG vs. KO \(^{*P < 0.05}\)). (C) Average values of Ca\(^{2+}\) transient amplitude \(^{*P < 0.05}\) TG and HETxTG vs. WT. (D) Representative traces of Ca\(^{2+}\) transients evoked with 10 mM caffeine in the WT, HETxTG, and the KOxTG myocytes. (E) Average values of caffeine-induced Ca\(^{2+}\) transients \(^{*P < 0.05}\) TG vs. WT). (F) Representative line-scan images and temporal profiles of Fluo-3 fluorescence at baseline and in the presence of ISO in the HETxTG myocytes stimulated at 0.5 Hz. (G) Average data of diastolic Ca\(^{2+}\) release events at baseline and in the presence of ISO in the HETxTG myocytes \(^{*P < 0.05}\). Experiments were performed at room temperature (RT) with 1 mM Ca\(^{2+}\) in the external solution. (HET, heterozygous and KO, knockout for CASQ2; TG, expresses SERCA1a transgene).
The effects of ISO on Ca^{2+} handling were investigated in the HETxTG myocytes (Figure 4F and G). At baseline, the myocytes exhibited occasional spontaneous releases of different sizes from small wavelets to full waves. All spontaneous release events were grouped into three categories according to their size (i.e. full waves and wavelets with width of either ≥ 10 μm or 5–10 μm) (Figure 4G). ISO caused a marked increase in the rate of occurrence of all types of events including full Ca^{2+} waves.

3.6 Increased cardiomyocyte apoptosis in CASQ2-deficient mice overexpressing SERCA1a

Collectively, the data presented above indicate that weakening of in vivo mechanical performance of double-mutant hearts occurs without a corresponding weakening of systolic Ca^{2+} release and contractile force in cardiac myocytes. This apparent discrepancy could be explained by increased myocyte loss leading to LV chamber dilation, a possibility also consistent with the significant LV dilation revealed by our histological analyses (Figure 1E). TUNEL staining of tissue sections from both the HETxTG and the KOxTG hearts displayed significant increases in the fraction of apoptotic nuclei [0.6 and 0.9%, respectively (P < 0.05)] compared with the WT and the KO groups (0.1%; P < 0.05) (Figure 5A). Additionally, expression of the pro-apoptotic form of Caspase 3 (17 kDa fragment) was significantly increased in the HETxTG (one fold; P < 0.05) and KOxTG (1.7 fold; P < 0.05) mice compared with the WT and the KO hearts, respectively. (Figure 5B). Thus, myocyte loss could indeed contribute to the in vivo cardiac contractile dysfunction in double-mutant mice by reduced myocyte number and increased LV diameter, thereby reducing LV pressure (see ‘Section 4’).
3.7 Combining CASQ2 ablation with either ablation of PLB or expression of SERCA1a produces similar phenotypes

Despite lack of detrimental effects of SERCA1a expression on cardiac function, by itself or even in combination with ablation of PLB, this exogenous SERCA isoform might not be considered fully compatible with cardiac myocytes. Therefore, confirmatory experiments were performed in a new mouse model of increased diastolic Ca\(^{2+}\) release by crossing CASQ2.KO mice with mice deficient in PLB, the endogenous inhibitor of SERCA2a (DKO). We found that this DKO model reproduces the main findings obtained with KOxTG and HETxTG mice including early mortality (average dying age 12 ± 0.4 months, \(n = 19\)), cardiac contractile dysfunction, hypertrophy, severe chamber dilation [HW/BW ratio: WT (5.00 ± 0.22), DKO (15.00 ± 3.27, \(P < 0.05\)), pulmonary congestion (LW/BW ratio: WT (5 ± 0), DKO (12 ± 2, \(P < 0.05\)), abnormal myocyte Ca\(^{2+}\) cycling (Figure 6), and increased Caspase 3 fragments (Figure 5B). Although the results were qualitatively similar, the DKO mice lived relatively longer than the HETxTG and the KOxTG mice, indicating that the number of active pumps could play a significant role in modulating the magnitude of RyR2 leak and hence its deleterious effects.

4. Discussion

In the present study, we investigated the consequences of combining dysregulated RyR2 function with facilitated SR Ca\(^{2+}\) uptake by crossing genetically altered mice deficient in expression of CASQ2 with mice overexpressing SERCA1a (or ablation of PLB, a negative regulator of SERCA2a). Myocytes from the crossbred mice displayed increased diastolic Ca\(^{2+}\) release with preserved myocyte systolic Ca\(^{2+}\) release and contractility. Strikingly, the hybrid mice died prematurely and developed cardiac failure characterized by enhanced myocyte apoptotic death, hypertrophic chamber dilation, and haemodynamic deficiency. These findings present important implications for the pathophysiology and treatment of HF.

4.1 Diastolic SR Ca\(^{2+}\) release as a cause of HF

Although dysfunctional RyR2s have been associated with HF and exacerbation of the disease phenotype in pressure-overload induced HF, it is unknown whether chronic SR Ca\(^{2+}\) leak by itself can trigger pathological downstream changes leading to HF. Notably, gain of function RyR2 mutations associated with ‘leaky’ RyR2 channels have not been shown to cause HF. In the present study, we demonstrate that a chronic increase in diastolic RyR2-mediated SR Ca\(^{2+}\) release can lead to a severe cardiac mechanical dysfunction and hypertrophy, thus providing strong support for the notion that excessive diastolic SR Ca\(^{2+}\) release through RyR2s can cause HF. At the same time, our results demonstrate clearly that, because of the self-limiting nature of diastolic release via RyR2s, chronically elevated Ca\(^{2+}\) release that is large enough to cause HF can be attained only under conditions of facilitated SR Ca\(^{2+}\) uptake. According to previous longitudinal studies, in a tachypacing model of HF, RyR2-mediated leak that results from hyperphosphorylation and oxidation of the RyR2 presents one of the earliest alterations in myocyte Ca\(^{2+}\) handling. Similarly, increased \(\beta\)-adrenergic stimulation of the heart expected to increase SR Ca\(^{2+}\) uptake (via PLB phosphorylation) typically occurs early, during the compensatory phase of HF development and has been shown to persist through up-regulation of the \(\beta 2\) adrenoreceptors at more advanced stages. Therefore,
on the basis of our findings, altered RyR2 function would be expected to causally contribute to HF but only when coinciding with adrenergically mediated increase in SR Ca\(^{2+}\) uptake, thus potentially contributing to the heterogeneity of HF aetiology in various pathological settings.\(^{24}\)

### 4.2 LV remodelling due to cell loss and hypertrophy but with preserved myocyte contractility causes haemodynamic impairment in Ca\(^{2+}\)-dependent HF

Decreased cardiomyocyte SR Ca\(^{2+}\) content and weakened systolic SR Ca\(^{2+}\) release and contractility are considered to be important characteristics of the failing heart, and indeed, contractile dysfunction in HF is commonly attributed to depressed myocyte contractility, i.e. myocyte failure.\(^{25–27}\) Our results show that decreased systolic SR Ca\(^{2+}\) release and weakened myocyte contractility are not essential for HF development. Notably, because of the facilitated SERCA-mediated SR Ca\(^{2+}\) re-uptake, SR Ca\(^{2+}\) load, systolic Ca\(^{2+}\) release, and contractile force were preserved, or even improved, in intact muscles and isolated ventricular myocytes from the double-mutant mice compared with the WT and the KO hearts despite the substantial diastolic loss of SR Ca\(^{2+}\) in the double mutants (Figures 3 and 4). Furthermore, our data demonstrate that under conditions of sustained RyR2-mediated diastolic release, HF can develop without signs of myocyte contractile failure as a result of myocyte loss and dilatation of the LV chamber. Indeed according to the Laplace’s law, ventricular pressure will fall with increasing chamber diameter and wall thickness even if wall tension due to myocyte contraction is preserved. Notably, the \(\sim 50\%\) increase in end-diastolic LV diameter and the \(\sim 20\%\) decrease in LV wall thickness observed in the HETxTG mice at a constant wall tension translate into nearly two-fold decrease in systolic LV pressure consistent with the \(\sim 2.5\)-fold decrease in ejection fraction in these mice (Figure 2).

It is well established that mitochondrial Ca\(^{2+}\) overload results in mitochondrial injury associated with myocyte apoptosis or necrosis.\(^{28–30}\) In addition, several major signalling pathways have been implicated in the activation of the cardiac hypertrophic response following elevations of intracellular Ca\(^{2+}\), including the calcineurin/NFAT and the CaMKII/HDAC pathways.\(^{31–33}\) Despite their important role in the development of cardiac pathological remodelling, the exact subcellular sources of Ca\(^{2+}\) involved in mitochondria-mediated cell death and Ca\(^{2+}\)-dependent hypertrophy remain poorly defined. Our results clearly point to a role for SR-derived Ca\(^{2+}\) in these pathological processes.

### 4.3 Increased SR Ca\(^{2+}\) uptake and arrhythmogenesis in CPVT

In CPVT, episodes of arrhythmia are provoked by exercise or emotional stress associated with increased levels of circulating catecholamines in both patients and genetic mouse models of this syndrome.\(^3\) Although the catecholamine-dependency of CPVT is likely to have complex causes, it has been suggested that stimulation of SERCA2a (via phosphorylation of PLB) is a potential mechanism for the pro-arrhythmic effects of catecholamines.\(^3,4,34\) Facilitated SERCA-mediated SR Ca\(^{2+}\) uptake is expected to increase myocyte arrhythmic potential by maintaining the SR Ca\(^{2+}\) content at levels conducive to spontaneous Ca\(^{2+}\) release generation. Consistent with this expectation, CASQ2-deficient myocytes overexpressing SERCA1a exhibited a higher propensity for spontaneous SR Ca\(^{2+}\) release than either the WT or the KO myocytes in the absence of \(\beta\)-adrenergic stimulation (Figure 4). Surprisingly, increased spontaneous SR Ca\(^{2+}\) release propensity did not translate into higher arrhythmia vulnerability in double-mutant mice under baseline conditions (no ISO). However, the severity of arrhythmias provoked by ISO was markedly exacerbated in the double-mutant mice compared with the KO mice (see Supplementary material online, Figure S1). Other factors such as functional heterogeneities in the heart during catecholamine stimulation\(^35\) (as opposed to homogeneous functional changes resulting from cardiac expression of SERCA1a) seem to be required to provide a necessary substrate for arrhythmias. Further studies will have to look into this important issue.

### 4.4 SERCA up-regulation as therapy for HF

Up-regulation of SR Ca\(^{2+}\) re-uptake through expression of SERCA2a or ablation of PLB are promising gene therapy approaches based on their beneficial effects in a number of animal models of HF.\(^36,37\) Despite many successful examples, this approach has failed to reverse HF or has even exacerbated cardiac dysfunction in some studies.\(^38–40\) Our results demonstrate that up-regulation of SERCA-mediated SR Ca\(^{2+}\) uptake either directly increasing the number of SERCA pumps or by disinhibition of endogenous SERCA pumps via ablation of PLB, when combined with dysregulated RyR2s, can be severely detrimental rather than therapeutic. RyR2s are known to become hyperactive or ‘leaky’ in certain HF settings as a result of post-translational modifications through phosphorylation and/or oxidation.\(^6,27,41\) Our data suggest that SERCA therapy should be advocated with caution in failing hearts given the possibility of pathological interaction of facilitated SR Ca\(^{2+}\) uptake with dysregulated RyR2 function.

### 4.5 Potential limitations

A potential limitation of this study is that SERCA1a, normally absent in cardiac myocytes, might be considered ‘non-physiological’ and therefore detrimental to cardiac function. However, as shown previously, SERCA1a can functionally substitute SERCA2a in the cardiac muscle without detrimental changes in phenotype.\(^33\) Additionally, when we used ablation of PLB to facilitate SR Ca\(^{2+}\) uptake against the background of CASQ2.KO, we obtained results similar to those attained in our original double-mutant strains. It is also to be noted that as in all studies involving manipulation of individual genes, changes in SERCA1a and CASQ2 are likely to be associated with alterations in expression/activity of other proteins; thus, we cannot rule out the possibility of such compensatory changes influencing our results.
