Tumor necrosis factor receptor II (TNFRII) is one of the TNF receptor superfamily members and our recent pathological studies show that TNFRII is deficient in the brains of Alzheimer’s disease (AD). However, the mechanisms of TNFRII in AD pathogenesis remain unclear. In the present study, by using the gene-targeting approach to delete TNFRII in AD transgenic mouse model, we found that, in the brain of APP23 mice with TNFRII deletion (APP23/TNFRII²/²), AD-like pathology, i.e. plaque formation and microglial activation, occurs as early as 6 months of age. To test whether the increased levels of Aβ plaques was due to elevated Aβ, we measured Aβ and found that Aβ levels indeed were significantly increased at this age. Because β-secretase, BACE1, is critical enzyme for Aβ production, we have examined BACE1 and found that BACE1 is increased in both protein levels and enzymatic activity as early as 6 months of age; Having shown that BACE1 promoter region contains NF-κB binding sites, we found that cytoplasmic NF-κB was elevated and SUMO1 binding to IκBα was decreased. To further verify these findings, we have overexpressed TNFRII and identified that overexpressing TNFRII can reverse the findings from APP23/TNFRII²/² mice. Altogether, our results demonstrate novel roles of TNFRII in the regulation of Aβ production, suggesting a potential therapeutic strategy for AD by up-regulating TNFRII levels and elevating phosphorylated IκBα by SUMOylation.

INTRODUCTION

Pathologically, AD brains can be identified by the progressive formation of insoluble amyloid plaques that are composed of amyloid β-peptide (Aβ) fragments, which are proteolytically derived from the larger amyloid precursor protein (APP). Aβ peptide was produced by two proteolytic enzymes, β- (BACE1) and γ-secretase. APP is firstly cleaved by BACE1 at the N-terminus of the Aβ domain (1–4). This cleavage generates the soluble APPβ (sAPPβ) and C99 fragments, which undergo a second cleavage by γ-secretase (3,5–7). γ-Secretase cleavage is not precise and produces a spectrum of Aβ peptides that vary in length by a few amino acids at the carboxyl terminus (8).

Prominent activation of inflammatory processes and innate immune responses are observed in AD brain samples (9–13). Particularly, microglia are activated at the sites of amyloid deposits in the AD brain and release a variety of pro-inflammatory mediators which contribute to further neuronal dysfunction and even cell death (14–17). TNFα, one of pro-inflammatory cytokines, exerts its cellular effects through two distinct receptors—type I and type II of TNF receptors (TNFRI and TNFRII). The two receptor subtypes are similar in their extracellular regions because each contains four cysteine-rich repeat domains. However, they are structurally different (78% differences in amino acid sequences) in their intracellular regions, indicating possible distinct biological functions and intracellular signal transduction pathways. Recently we found (18) that TNFRI deletion decreased Aβ peptide generation by inhibiting BACE1 levels via the NF-κB pathway. Moreover, we recently found that TNFRII is deficient in AD brains (19).

Whether and how TNFRII plays a role in AD pathogenesis is unknown. In this study, we knocked out TNFRII gene in transgenic APP23 mice and found that Aβ plaque number and levels dramatically increase as early as 6 months of age. We also found increases in both BACE1 protein level and enzyme activity. And the promotion of BACE1 could be reversed by overexpressing TNFRII. Interestingly, we found that the deletion of TNFRII results in the de-SUMOylation of IkBα; NF-κB complexes, which destabilizes the NF-κB complex and enhances NF-κB dissociation and translocation into nuclei.

RESULTS

Amyloid plaque formation is elevated in APP23/TNFRII−/− mice

APP23 transgenic mice with 7-fold human APP mutations over-produce Aβ, Aβ40 and Aβ42, and develop significant amyloid deposits by 14 months of age (20). To explore the possibility of TNFRII roles in Aβ plaque formation, we generated APP23/TNFRII−/− mice by crossing APP23 mice with TNFRII knockout mice (TNFRII−/−) (21). Using immunohistochemical staining, we examined the brain sections with an anti-Aβ monoclonal antibody 6E10 (3,22), and observed that, at 12 months of age (Fig. 1A–D), APP23 mice displayed numerous Aβ plaques throughout the cortex and hippocampus, which was consistent with previous reports (18,20). Interestingly, in APP23/TNFRII−/− mice, Aβ plaques were visualized as early as 6 months of age (Fig. 1A and B). However, these Aβ plaques were rarely observed in APP23 mice at this time point (Fig. 1A and B, *P < 0.01). At 9 and 12 months of age, although both APP23 and APP23/TNFRII−/− mice displayed large amounts of Aβ plaques in the cortex and hippocampus regions, a significant increase in the number of Aβ plaques were seen in APP23/TNFRII−/− brains (Fig. 1C and D, *P < 0.01) compared with age-matched APP23 mice, indicating that the genetic deletion of TNFRII gene might be the cause of early onset of Aβ plaque formation and increased number of Aβ plaque. At 3 months of age, neither APP23 nor APP23/TNFRII−/− mice displayed signs of Aβ plaque formation (data not shown).

Microglia activation is increased in APP23/TNFRII−/− mice

Microglia activation is another hallmark of Aβ pathology progression (23–25). Using CD45 and CD11b, two well-characterized microglia activation markers (23–25), we observed whether there were more activated microglia in APP23 mouse brains with TNFRII−/− deletion. Without Aβ plaque formation, neither APP23 nor APP23/TNFRII−/− mice displayed any CD45 staining at 3 months of age, indicating that the activation of microglia could not be obviously observed without Aβ plaque formation. At 6 months of age, while APP23 mice exhibited light CD45 positive staining (Fig. 1E), APP23/TNFRII−/− mice had greatly increased number of CD45 positive cells in the cortex and hippocampus (Fig. 1E). At 12 months of age, both APP23 and APP23/TNFRII−/− mice illustrated extensive immunoreactivity with antibodies against CD45 in the cortex and hippocampus (Fig. 1F), which was consistent with previous reports (18,26).

Aβ production is elevated in APP23/TNFRII−/− mice

To examine whether early onset of Aβ plaque formation and increased numbers of Aβ plaques in APP23/TNFRII−/− mice was due to changes of Aβ production, we measured levels of total Aβ40, Aβ40 and Aβ42 in APP23 and APP23/TNFRII−/− mouse brains (n = 10 for each group). Consistent with the results of the increased numbers of Aβ plaques, total Aβ1−42 levels were elevated at 6 months of age in APP23/TNFRII−/− mice compared with APP23 mice (Fig. 2A, *P < 0.05, **P < 0.01). The increase tendency of total Aβ1−42 levels was merged until 12 months of age in APP23 and APP23/TNFRII−/− mice (Fig. 2A, **P < 0.01). Next, we measured the levels of Aβ40 and Aβ42, two major components of Aβ peptide during aggregation, and the ratio of Aβ42/Aβ40 which was correlated with Aβ aggregation (27,28). We found a steady increase in soluble Aβ40 level from 3 to 12 months of age in APP23 mice (Fig. 2B). However, there was 46% decrease in soluble Aβ40 level in 6-month-old APP23/TNFRII−/− mice compared with age-matched APP23 mice (Fig. 2B, **P < 0.01). No significant differences of soluble Aβ40 level were found between other age groups examined (3, 9 and 12 months old). We also found a significant decrease in soluble Aβ42 levels exclusively in 6-month-old APP23/TNFRII−/− mice (Fig. 2C, **P < 0.01). To measure insoluble Aβ40 and Aβ42, as we described in the Materials and Methods, the insoluble pellets from centrifugation of brain homogenates with radioimmunoprecipitation buffer (RIPA) buffer were dissolved in formic acid and, then insoluble Aβ40 and Aβ42 protein levels were measured by enzyme-linked immunoabsorbent assay (ELISA) kits. A corresponding 2-fold increase in insoluble Aβ42 levels was observed in APP23/TNFRII−/− mice compared with APP23 mice at the age of 6-, 9- and 12-months old, except 3 months of age (Fig. 2D, *P < 0.05, **P < 0.01). Similar results were obtained for insoluble Aβ42 level, except at the group of 12 months old (Fig. 2E, *P < 0.05, **P < 0.01).

BACE1 levels and enzymatic activity, but neither γ-secretase nor Aβ degradation enzymes, are elevated in APP23/TNFRII−/− mice

There are three possible mechanisms that account for increased Aβ production in APP23/TNFRII−/− mice. The first is altering APP protein levels; the second is the activity changes of enzymes involved in Aβ production, such as BACE1 and γ-secretase; the third is the changes of the degradation enzymes neprilysin (NEP) and insulin degradation enzymes (IDE). We examined the expression levels of APP, BACE1, γ-secretase, NEP and IDE at different age stages in wild type (WT), APP23 and APP23/TNFRII−/− mice. Results showed similar APP levels in both APP23/TNFRII−/− and APP23 mice at all age groups (data not shown), suggesting that the difference in soluble and insoluble Aβ40 and Aβ42 levels between APP23/TNFRII−/− and APP23 mice was not due to a change in APP protein levels. The only differences observed in our western blots were the levels of BACE1. Corresponding to increased Aβ levels and amyloid plaques in APP23/TNFRII−/− mice, significant increases in BACE1 levels began as early as 6 months in APP23/TNFRII−/− mice compared with age-matched APP23 mice (Fig. 3A). Increased BACE1 levels were seen in the mice.
Figure 1. TNFRII deletion increased amyloid plaque formation early as 6 months old in APP23 mice. (A) Brain sections through the cortex and hippocampus from 6-month-old APP23 and APP23/TNFRII<sup>−/−</sup> mice were immunostained with anti-Aβ monoclonal antibody 6E10. Amyloid plaques were observed in APP23/TNFRII<sup>−/−</sup> mice in both the cortex and hippocampus while no obvious amyloid plaques in APP23 mice. (B) Stereological double blinded analysis by two independent researchers revealed increased amyloid plaques in the cortex and hippocampus in APP23/TNFRII<sup>−/−</sup> mice compared with APP23 mice. (C) Brain sections through the cortex and hippocampus from 12-month-old APP23 and APP23/TNFRII<sup>−/−</sup> mice were immunostained with anti-Aβ monoclonal antibody 6E10. Amyloid plaques in both the cortex and hippocampus were observed in both APP23 and APP23/TNFRII<sup>−/−</sup> mice, with more amyloid plaques in APP23/TNFRII<sup>−/−</sup> mice. (D) Stereological analysis revealed increased amyloid plaques in cortex and hippocampus in APP23/TNFRII<sup>−/−</sup> mice compared with APP23 mice of 12 months. Cell nuclei were counterstained with DAPI. *P < 0.01. (E) Immunostaining revealed a clear CD45 staining in 6-month-old APP23/TNFRII<sup>−/−</sup> mice while no staining was observed in age-matched APP23 mice. (F) An extensive CD45 staining in the cortex and hippocampus was observed in both APP23 and APP23/TNFRII<sup>−/−</sup> mice with much more visible staining in APP23/TNFRII<sup>−/−</sup> mice. Bars: 50 μm.
through 12 months. Combining the data, increased Aβ production might be due to the increased APP processing by an increased expression of BACE1.

Next, we analyzed BACE1 enzymatic activity (18,29–31) and found an significant increase in BACE1 activity at the age of 6 months in APP23/TNFRII+/− mice when compared with APP23 mice. Similar to the results of BACE1 protein changes, enzymatic activity continued to increase through the 12th month of age in APP23/TNFRII+/− mice (Fig. 3B), indicating that TNFRII deletion not only increases BACE1 expression level but also elevates BACE1 enzymatic activity. This may be the cause of more Aβ production from increased APP processing by BACE1.

To further explore whether increased BACE1 protein levels were regulated at the transcriptional level or just at the translational level, we performed reverse transcriptase-polymerase chain reaction (RT-PCR) to measure BACE1 mRNA levels and found increased levels in 6-, 9-, and 12-month-old groups of APP23/TNFRII+/− mice compared with APP23 mice (Fig. 3C). There were no significant changes among the 3-month-old group (Fig. 3C), consistent with the results from western blots (Fig. 3A). This indicated that the genetic deletion of TNFRII increased BACE1 protein levels through enhanced transcriptional regulation.

The levels of enzyme activities for NEP and IDE were not changed at all age groups of APP23/TNFRII+/− mice compared with levels in APP23 mice (Fig. 4A–D). The results indicate that the clearance mechanism of Aβ is not related to increased Aβ levels found in APP23/TNFRII+/− mice. The catalytic subunit of γ-secretase complex, PS1, did not reveal any differences between APP23/TNFRII+/− and APP23 mice at all age groups that were studied (data not shown).

**BACE1 transcription and expression are reduced in TNFRII overexpressed cells**

To confirm the suppressive regulation of TNFRII in BACE1 regulation, we transiently transfected APP stable cells with pFlag-CMV-TNFRII and measured the levels of Aβ40 and Aβ42 in the conditioned medium. Interestingly, we found a decreased level of Aβ40 and Aβ42 peptides in the TNFRII overexpressed cells (Fig. 5A and B). We also detected the protein levels involved in Aβ production. Similar to the results obtained from our TNFRII knockout mice; we found that neither γ-secretase subunit PS1 nor Aβ clearance enzymes NEP and IDE changed (Fig. 5H). Expectedly, we found a decreased BACE1 level in TNFRII overexpressed cells (Fig. 5C), along with a significant decrease in BACE1 enzymatic activity (Fig. 5D, *P < 0.01), when compared with the controls. To
validate the effect of TNFRII on BACE1, the levels of sAPPβ in the conditioned medium were detected. We found a decreased sAPPβ level in TNFRII transfected cells (Fig. 5E). We also measured the mRNA level of BACE1 and found that, in agreement with our results obtained from western blots (Fig. 5E), BACE1 mRNA levels decreased accordingly after TNFRII overexpression (Fig. 5F).

To further confirm TNFRII role in the transcriptional regulation of BACE1, we transfected HEK293T cells with a pBIP-A vector containing a BACE1 promoter (−1941 to +292) that was upstream of a luciferase reporter gene (32,33) together with pFlag-CMV-TNFRII. Expectedly, we found a significant decrease in BACE1 promoter activity in TNFRII overexpressed cells (Fig. 5G, *P < 0.01), indicating that TNFRII affects BACE1 promoter and inhibits its transcription.

**Genetic deletion of TNFRII results in elevation of NF-κB nuclear translocation via decrease of SUMOylation**

A line of evidences showed that NF-κB was involved in TNFRII-mediated signal transduction pathway (34–36), and was bound to BACE1 promoter-specific NF-κB site (37). To explore the subcellular distribution of NF-κB, we immunostained with an antibody against the p65 subunit of NF-κB, and results showed an increased expression level of NF-κB in the nuclei of TNFRII−/− brains (Fig. 6A). In non-stimulated cells, NF-κB is sequestered by IκBα in cytoplasm; stimulation of various inducers cause IκB phosphorylation and subsequent degradation, liberating NF-κB and transporting into nuclei (18). One possible explanation is that increased nuclear NF-κB levels is due to an increase in NF-κB release from complex IκBα:NF-κB. Small ubiquitin-related modifier (SUMO) is the ubiquitin-like protein family (38–41). The covalent attachment of SUMOs (SUMOylation) to target proteins is analogous to ubiquitination. IκBα SUMOylation may stabilize IκBα:NF-κB complex and decrease NF-κB release through preventing ubiquitination by E2 (42–44). We double stained brain sections of TNFRII−/− mice with antibodies against p-IκB and SUMO1. Results showed decreased p-IκB levels and decreased co-localization of SUMO1 and p-IκB (Fig. 6B). We further examined the SUMO1 expression by western blot and found no significant level changes between the controls and TNFRII−/− brains, suggesting that TNFRII deletion reduces SUMO1 binding to IκB protein but not elevates SUMO1 level. However, when we tested another member of SUMOs, SUMO-4 (43,44), a significant decrease in SUMO-4 level was observed in TNFRII−/− brains (Fig. 6C). Together, our results suggest TNFRII is correlated with the SUMO changes of binding capacity to IκB. Whether the SUMOylation affects IκBα expression and its phosphorylation is still unknown. We tested the expression levels by western blot, and slight but insignificant increases in IκBα and IKKα were present, along with a significant decrease in p-IκBα (Fig. 6C).

**Overexpression of TNFRII prevents NF-κB nuclear translocation by increase of SUMOylation**

To further confirm the changes of NF-κB and SUMOs observed in TNFRII−/− brains, we overexpressed TNFRII and found a decreased expression level of NF-κB in nuclear extraction (Fig. 7A). Accordingly, an increased NF-κB level was observed in cytoplasm (Fig. 7B). The finding was also demonstrated by
immunohistostaining (Fig. 7C). Meanwhile, we observed a significant increase in p-I\(\kappa B\) protein levels, but no significant change in non-phosphorylated I\(\kappa B\) (Fig. 7B); these results suggest that NF-\(\kappa B\) signaling is activated in these conditions.

Figure 4. Deletion of TNFRII gene on APP23 transgenic mice has no effect on NEP or IDE protein expression levels and enzymatic activity. (A)–(D) Western blot studies show that little changes of protein expression of NEP and IDE in brains among APP23/TNFRII\(^{-/-}\), APP23 and WT mice at ages of 3, 6, 9 and 12 months old although protein levels of NEP and IDE decline in all of groups as age increases. Furthermore, no significant changes were observed in NEP (E) and IDE (F) enzymatic activity among APP23, APP23/TNFRII\(^{-/-}\) and WT mice at all ages. Error bars represent standard deviation.

Figure 5. TNFRII overexpression reduces A\(\beta\)40 and A\(\beta\)42 levels. (A) A\(\beta\)40 levels in the culture medium reduced after overexpression of TNFRII in APP stable cell line. (B) A\(\beta\)42 levels in the culture medium decreased with overexpression of TNFRII in APP stable cell line. (C) BACE1 level significantly decreased in TNFRII overexpressed cells. (D) BACE1 enzymatic activity decreased in TNFRII overexpressed cells. (E) sAPP\(\beta\) levels in the culture medium reduced after overexpression of TNFRII in APP stable cell line. (F) BACE1 mRNA levels decreased in TNFRII overexpressed cells. (G) Luciferase activity assay showed a decreased BACE1 promoter activity with TNFRII overexpression. Data were presented as an arbitrary unit to \(\beta\)-galactosidase enzyme and shown as mean \pm SEM.
were further confirmed by immunocytochemistry with antibodies against SUMO1 and p-IκBα (Fig. 7D). One possible explanation of why the NF-κB and p-IκBα levels increased in cytoplasm is that SUMO1 keeps complex IκBα;NF-κB stability. Images showed increased co-localization of SUMO1 and p-IκBα in TNFRII overexpressed cells (Fig. 7D). The results suggest that TNFRII-induced SUMOylation plays a role in the decreased release of NF-κB from complex IκBα;NF-κB.

**DISCUSSION**

We observed that genetically deleting TNFRII in APP23 mice resulted in premature and more amyloid plaques due to the up-regulation of BACE1 protein levels and activities. In contrast, TNFRII overexpression inhibited BACE1 transcription by limiting NF-κB nuclear translocation. TNFRII inhibition of NF-κB release is due to enhancing SOMOylation of IκB;NF-κB complex. These findings provide evidence that TNFRII plays a beneficial role in AD, and without it, early onset of amyloid plaques would occur.

NF-κB belongs to a family of ubiquitously expressed Rel-related transcription factors and is activated by the proteolytic degradation of inhibitors from NF-κB (IκBs) in the cytoplasm. Once activated, NF-κB is translocated to the nuclei and exerts its function on gene transcription. BACE1 promoter contains a number of putative transcription factor binding sites, including Sp1, NF-κB, YY1, MZF1, HNF-3β and four GATA sites, and is highly conserved between rats, mice and humans (3,6,33). A detailed analysis using BACE1 promoter constructs carrying NF-κB site mutations revealed a unique cell type-specific regulation of BACE1 promoter activity (6). We found that NF-κB has a bilateral role in the regulation of BACE1 promoter activity in different cell types. In neuroblastoma cells, such as SH-SY5Y cells or PC12 cells, NF-κB acts as a suppressor under basal conditions. In the situation of exposing soluble Aβ peptides to neurons or activation of glial cells by TNF-α, however, NF-κB acts as an activator on BACE1 expression (37). In the present study, we found that NF-κB played an activating role in BACE1 promoter in APP23 mice, consistent with our previous results (18).

Overall, inflammatory changes are observed in AD brains, particularly around amyloid deposits, which are rich in activated microglia. Immunocytokine TNFα is a central mediator of inflammation, immune response and antiviral defense (45,46). TNFα binds and signals through two distinct receptors, TNFR1 and TNFRII, and are capable of activating NF-κB through different mechanisms (34–36). Our previous study illustrated that TNFRI signaling could directly regulate BACE1 transcription through NF-κB pathway (18). Here, we suggested that TNFRII could also directly regulate BACE1 transcription through NF-κB pathway. However, the regulations of TNFRI and TNFRII on the activation of NF-κB were quite different. It has been suggested that TNFRI is capable of activating NF-κB through its Fas-associated death domain protein (FADD)/TNFR1-associated death domain protein (TRADD) interaction (34). However, the exact signal transduction pathway in the TNFRII-mediated activation of NF-κB is still unclear. It is possible that RIP, NIK, JNK and other molecules might be involved in TNFRII-NF-κB
Figure 7. TNFRRII overexpression decreases nuclear NF-κB translocation by decreasing SUMO1 binding to IκBα. (A) Changes of intranuclear NF-κB levels using western blot in TNFRRII transfected cells. PARP was used as a loading control for the nuclear fraction. (B) Changes in the cytosolic levels of NF-κB, IκBα and p-IκBα levels using western blots in TNFRRII overexpressed cells. β-actin was used as a loading control for the cytoplasmic fraction. (C) Immunofluorescent images of changes in phosphorylated IκBα (p-IκBα) in TNFRRII overexpressed cells. (D) Changes in co-localization of p-IκBα and SUMO1 in TNFRRII transfected cells using immunofluorescent staining. Cell nuclei were counterstained with DAPI. Bars in C and D: 10 μm.
pathway (34). The ability of TNFRI to activate NF-κB appears to account for majority of TNFα-stimulated NF-κB activation, while TNFRII-stimulation accounts for ~10% of the achievable TNFR-stimulated NF-κB activity (34). It suggests that TNFRII is not only a ligand passing protein, but it is also actively involved in NF-κB activation. There has been reported that TNFRII could lead to the activation of NF-κB even in the absence of the ligand (47,48).

Here, we found that, however, in TNFRII deletion brains, NF-κB levels are not decreased but increased, conversely, which resulted from IkB;NF-κB SUMOylation. Ubiquitin and the individual SUMO family members are all targeted to different proteins with diverse biological functions. Ubiquitin predominantly regulates degradation of its target proteins (41). SUMO1 is an ubiquitin-like protein, which binds to a wide range of target proteins. SUMO1 is conjugated IkBα to regulate nuclear trafficking and protein stability (42). SUMO-1-modified IkBα cannot be ubiquitinated and function as an antagonist of ubiquitin in the proteasome-mediated degradation process. As a result, over-expression of SUMO-1 inhibits signal-induced activation of NF-κB-dependent transcription (42). In the present study, we discovered that TNFRII was able to reduce NF-κB release by SUMOylation of IkBα;NFκB complex. SUMO4 is another member of the SUMO gene family. It is located in the cytoplasm and specifically modifies IkBα, leading to negative regulation of NF-κB-dependent gene transcription (43,44). SUMO4 expression in TNFRII−/− brains is much lower than in WT controls, also suggesting TNFRII role in stabilizing NF-κB in cytoplasm. Our observation in TNFRII deletion or overexpression suggested that one of the physiological functions of TNFRII is primarily the maintenance of IkBα;NF-κB stability. It may be partly explained that even if TNFRII is stimulated, due to prevention from NF-κB release, the NF-κB activation response is at a lower level (~10% compared with TNFRII-stimulation) (34). It also suggest that the activation of NF-κB may be elevated to a limited level in spite of the activation of TNFRII-NF-κB pathway.

Collectively, genetic deletion of TNFRII resulted in NF-κB accumulation in the nuclei due to a decrease in the binding of SUMOs to IkB;NF-κB, which elevated BACE1 transcription and led to an increase in BACE1 expression as well as BACE1 enzymatic activity. Accordingly, it increased cleavage of APP and led to an increase in BACE1 expression as well as BACE1 brain, which then influences APP or even tau cascade.

MATERIALS AND METHODS

Generation of APP transgenic mice with deletion of TNFRII

TNFRII knockout (TNFRII−/−) mice were of C57BL/6 background, constructed as previously reported (49). APP23 transgenic mice with human APP (751 isoform) cDNA harboring the Swedish double mutation (KM670/671NL) developed senile plaques in the cerebral cortex and hippocampus, along with neuronal loss at 18 months of age that was most evident in the hippocampal CA1 region (20). APP23 and TNFRII−/− mice were crossed and APP23+/TNFRII−/+ progeny were backcrossed with TNFRII−/− mice to generate APP23+/TNFRII−/− mice; such mice were further backcrossed to TNFRII−/− for six generations. The resulting APP23+/TNFRII−/− mice were used in the experiments. To keep the APP gene heterozygous, APP23 mice were continually crossed with C57BL/6 WT mice; the resulting mice were genotyped and APP positive mice were used in the experiments.

Immunohistochemistry

As previously described (18,50), paraformaldehyde-fixed brains were sectioned at 30 μm and incubated with 6E10 (Chemicon), CD45 and CD11b (Serotec). Immunodouble staining were performed with anti-NF-κB polyclonal antibody (Santa Cruz Biotech), anti-p-IκBα monoclonal antibody (Cell Signal), SUMO1 polyclonal antibody (Abcam), and counter staining with 4′,6-diamidino-2-phenylindole (DAPI) (Santa Cruz Biotech).

Enzyme-linked immunoabsorbant assay

APP23 and APP23/TNFRII−/− mice at 3, 6, 9 and 12 months of age were sacrificed, and half of the brain was homogenized in 1× RIPA buffer by a Dounce homogenizer; the supernatant resulting from 14 000 rpm centrifugation for 30 min was the soluble fraction. The insoluble pellet was dissolved in formic acid and neutralized by neutralization buffer (3M Tris Base). Sample protein concentration was quantitated by protein assay kit (Bio-rad).

For total Aβ1-42, ELISA, monoclonal 4G8 (Chemicon) was used as capture antibody and biotinylated 6E10 (Serotec) was used as detection antibody (3). Both Aβ40 and Aβ42 were measured by an Aβ40 and Aβ42 ELISA kit from Biosource following the manufacturer’s instructions.

Western blots

Fifty micrograms of total proteins were separated on sodium dodecyl sulphate-polyacrylamide gel electrophoresis gel and transferred to PVDF membrane. The blots were probed with following antibodies: anti-6E10 monoclonal antibody (R&D system); anti-BACE monoclonal antibody (R&D system); anti-PS1 N-terminus polypeptide antibody (gift from Dr Sangram Sidossi, University of Chicago); anti-IκBα monoclonal antibody (Santa Cruz Biotech); anti-IDE polyclonal antibody (Onco-gene); anti-NF-κB p65 polyclonal antibody, anti-IκBα polyclonal antibody (Abcam) and anti-PARP polyclonal antibody (Santa Cruz Biotech); anti-p-IκBα (S32 and S36) monoclonal antibody (Abcam), anti-SUMO1 (Abcam), anti-SUMO4 monoclonal antibody (Sigma) and anti-β-actin monoclonal antibody (Sigma).
BACE1 activity assay
An aliquot of brain homogenates from APP23, APP23/TFNRII+/- and WT mice was further lysed with a lysis buffer (10 mM Tris–HCl [pH 7.4], 150 mM NaCl, 1 mM EDTA, 1 mM Na3VO4, 10% Glycerol, 0.5% Triton X-100). BACE1 substrate (Biosource) was dissolved in DMSO and mixed with reaction buffer (50 mM HAc, 100 mM NaCl; pH 4.1). An equal amount of protein was mixed with 100 μl of substrate, and fluorescence intensity was measured with a microplate reader at an excitation wavelength of 320 nm and an emission wavelength of 390 nm.

Cloning and transfection
Human TNFRII was amplified by RT-PCR and then subcloned to pFlag-CMV vector (Sigma). We used 293 cells stably transfected with human APP695 (gift from Dr Dennis Selkoe from Brigham & Women’s Hospital, Harvard University) that were maintained in Dulbecco’s modified Eagle’s medium with 10% fetal bovine serum. APP695 stable cells were transfected with TNFRII expression vector by Effectene (Qiagen) according to the manufacturer’s instructions. Forty-eight hours after transfection, the conditional medium and cells were collected for Aβ ELISA, western blots and BACE1 activity assay as described above. The pCMX-IκBa plasmid was a gift from Dr Verman (Salk Institute for Biological Studies). It was co-transfected into APP695 stable cells with pFlag-CMV-TNFRII as described above.

RT-PCR
Total RNA was extracted from pFlag-CMV-TNFRII transfected APP695 stable cells by RNeasy mini kit from Qiagen. A one-step RT-PCR kit used was from Invitrogen for BACE1 detection.
For human BACE1 RT-PCR (475 bp), reverse primer 5'-CGT GGA TGA CTG TGA GAT GG and forward primer 5'-AGG GAG CAT GAT CAT TGG AG were used to amplify regions 696–1170 from BACE1 mRNA. For β-actin RT-PCR (462 bp), forward primer 5'-GGA CTT CGA GCA AGA GAT GG and reverse primer 5'-GAA GCA TTT TGG GTG GAG were used to amplify β-actin mRNA coding region from 633 to 1125. For mouse BACE1 PT-PCR (530 bp), forward primer 5'-CAG TGA AAG AAC ATG TTT TT and reverse primer 5'-CTA AAG GAT GCT GGG CAG AG were used to amplify BACE1 mRNA coding region from 1734 to 2263. Mouse s18 was used as a loading control; forward primer, 5'-CAG AAG GAC GTG AAG GTC CGT TTG TT and reverse primer, 5'-CAT GAT CAT TGG TGT GCT GA were used. The amplified mouse S18 fragment was 159 bp. Total RNA was extracted from the brains of WT, APP23 and APP23/TNFRII−/− mice at 3, 6, 9 and 12 months (n = 5 for each group) using an RNA mini column kit (Invitrogen). Real time PCR was performed at 51°C for 30 min for cDNA synthesis then 94°C for 30 s, 50°C for 30 s, 68°C for 1 min, for a total of 35 cycles.

Cell transfection and luciferase assay

We transfected 293T cells with pFlag-CMV-TNFRII and pB1P-A vector containing a BACE1 promoter (−1941 to +292) upstream from a luciferase reporter gene (32) using Effectene (Qiagen). Cells were collected 48 h after transfection, and a luciferase assay (Promega) was performed following the manufacturer’s instructions. As an internal control, PCH110 containing β-galactosidase enzyme was used. Luminescence intensity was measured with a microplate reader, normalized to the value of β-galactosidase enzyme, and plotted as an arbitrary unit.

Nuclear extraction

Nuclear fraction was extracted from APP695 stable cells transfected with pFlag-CMV-TNFRII using a nuclear extraction kit (Imgenex Corporation). Nuclear and cytoplasmic fractions were collected for the western blots of NF-κB, IkBa and p-IkBα. Poly (ADP-ribose) polymerase (PARP) was used as a loading control for nuclear fraction and β-actin was loading control for cytoplasmic fraction.

Quantitation of immunoreactive structures

Serial sagittal sections (30 μm) through the entire rostrocaudal extent of the hippocampus were cut on a cryostat. Every 10th section was immunostained with an anti-6E10 antibody. On all sections containing the hippocampus, we delineated the pyramidal cell layer CA1. The total number of Aβ-immunoreactive plaques was obtained using unbiased stereology (51,52) and a Leica microscope (Leica, Germany) equipped with a DEI-470 digital camera (Optronics, Goleta, CA). For each section, we delineated a 400 μm² area in the CA1 and cortex, and then counted all Aβ-immunoreactive plaques within that 400 μm² box. The average number of Aβ-immunoreactive plaques was calculated per animal (n = 10). We also measured the diameter of each counted plaque, and used the same method to count activated microglial cells (stained with CD45) in the hippocampus and cortex in a double blind manner. Differences between groups were tested with Image-pro Plus Analysis (MediaCybernetics, Silver Spring, MD).

Statistical analyses

Each experiment was performed independently at least three times, and the results were presented as mean ± standard error of mean (SEM). One-way analysis of variance (ANOVA) and Student–Newman–Keuls test, or t-test, was used to compare the differences between the means. A level of P < 0.05 was considered to be statistically significant.

AUTHORS’ CONTRIBUTIONS

H.J., P.H. performed biochemical and immunohistochemical experiments, participated in data analyses and wrote the manuscript draft. J.X. made valuable and critical suggestions and comments in physiology. M.S. provided APP23 transgenic mice through collaboration. Y.S. and R.L. initiated the project and designed the experiments, and participated in data analyses and overviewed manuscript drafting and finalized final version of the paper. All authors have read and approved the final manuscript.

ACKNOWLEDGEMENTS

We thank Dr Dennis Selkoe (Brigham Women’s Hospital, Harvard Medical School) for APP transfected cells, Dr Gang Yu (University of Texas Southwest) for APH1 and Dr Samgrum Sisodia (University of Chicago) for PS-1 antibody, Dr Kumar Sambamurti (Medical University of South Carolina) and Dr Weihong Song (University of British Columbia) for providing BACE1 short and long promoters.

Conflict of Interest statement. None declared.

FUNDING

This work was supported by National Institute on Aging (NIA)R01 (852888,032441), Arizona Biomedical Research Commission (ABRC)002, Alzheimer Association (IRRG-09-61521 and IIRG-0759510), American Health Assistance Foundation (AFAH) (G2006-118), 973 program in China (2011CB504102, 2012CB526703), the National Foundation of Natural Science of China (81171207) and Program for New Century Excellent Talents in University in China.
