Aims Atrial fibrillation (AFib) with a rapid ventricular response may adversely impact cardiac performance, especially in patients with heart failure. However, it remains uncertain whether rhythm irregularity per se has unfavourable effects apart from tachycardia, and whether rate regularization alone can improve heart function.

Methods and results Nine subjects with chronic AFib, atrioventricular nodal block, and symptomatic heart failure (ejection fraction 14–30%) were studied using a pressure–volume catheter. Ventricles were biventricularly paced (RV-apex, LV-lateral wall) at 80 or 120 min⁻¹ mean rate, using regular or irregular, Poisson-distributed stimulation. At 80 min⁻¹, ventricular function was similar between the two pacing modes. However, at 120 min⁻¹, irregular pacing impaired systolic (dP/dt max: −8.2%, P < 0.001) and diastolic function (dP/dt min: +21%, P < 0.001, LV end-diastolic pressure: +26%, P = 0.007) compared with regular rate pacing. Contractile function during irregular pacing varied with the ratio of preceding/pre-preceding intercycle (RR) interval (dP/dt max: 80 b.p.m.: r = 0.69; 120 b.p.m.: r = 0.74), whereas pre-load had little effect on instantaneous contractility.

Conclusion In heart failure subjects with AFib, RR-interval irregularity worsens cardiac function at elevated but not at normal range heart rate. Overall rate control is most important in these patients while rate regularization of rapid AFib may impart additional benefits.

Introduction

Atrial fibrillation (AFib) adversely affects cardiac haemodynamics by several mechanisms. Loss of atrial contraction can limit net filling and delay mitral valve closure augmenting pre-systolic regurgitation.¹ Diastolic filling is further impaired by short cycle lengths with rapid AFib, while persistent rate elevation can trigger systolic depression. Studies further suggest that rate irregularity itself may negatively impact cardiac performance.¹⁻³

Rate regularization can be achieved with overdrive right ventricular (RV)-pacing; however, any benefits are countered by the adverse effects of pacing-induced dys-synchrony.⁴⁻⁵ Biventricular or left ventricular (LV) free-wall pacing⁶ can diminish the latter, but such therapies are complex, making it important to determine whether there is indeed a net benefit from rate regularization and/or under what conditions it might occur.

Changes in ventricular performance with cycle length are due in part to varying diastolic filling time and to the force–frequency relation (FFR) that couples stimulation...
rate to contractile function.\textsuperscript{7,8} Beat-to-beat variability in cycle length (as with AFib) further affects both filling and contractility as a given beat can be premature relative to the prior cycle length (lower contractility and pre-load) or potentiated (opposite).\textsuperscript{9–11} Both the FFR and rate dependence of chamber filling are altered by dilated cardiomyopathy or hypertension.\textsuperscript{12} The former from abnormalities in calcium cycling\textsuperscript{12} and the latter due to depressed function and chamber remodelling. Whether this influences the impact of rate irregularity on net cardiac function remains unknown.

Accordingly, the present study tested whether rate irregularity itself is detrimental to LV function in patients with chronic AFib and heart failure, and directly examined the haemodynamic impact of rate regularization through biventricular pacing. We further tested whether the impact of rate regularization depends on mean heart rate and identified mechanisms by which function is specifically influenced by rate irregularity in the failing ventricle.

**Methods**

**Study group**

Nine patients (all males, age 65 ± 11 years) with chronic AFib and systolic dysfunction were studied. All were scheduled for pacemaker implantation for treatment of bradycardia with either a single RV lead or biventricular device. Clinical and echocardiographic features are summarized in Table 1. Patients were all on stable medical therapy for chronic heart failure consisting of a diuretic (n = 8), digoxin (n = 8), a β-blocker (n = 9), angiotensin converting enzyme or receptor blocker (n = 9), aldosterone receptor blocker (n = 3), nitrates or other vasodilator (n = 3). Seven had chronic left bundle branch block patterns on the surface ECG, one had bi-fascicular block and one a normal QRS. Six patients had undergone atrioventricular nodal ablation. The remainder had advanced nodal block requiring prior pacemaker implantation and were paced 100% of the time. The protocol complied with the Declaration of Helsinki and was approved by Johns Hopkins Joint Committee on Clinical Investigation. All patients provided signed informed consent.

**Protocol**

Patients were sedated with midazolam and fentanyl during the study. Multi-polar pacing electrode catheters were positioned in the RV apex and a lateral coronary vein. A dual-sensor pressure-volume catheter (Millar 550–768, Millar Instruments, Houston, TX, USA) was advanced through a femoral arterial sheath and positioned in the left ventricle to lie along the longitudinal axis. All pacing leads and pressure-volume sensors were linked to an external microprocessor-based stimulation system with data acquisition capability (FLEXTIM II, Guidant Inc., St Paul, MN, USA). The computer generated an AFib sequence with RR intervals following a Poisson distribution characteristic of the natural ventricular response to AFib.\textsuperscript{13} The sequence mean rate (80 or 120 min\textsuperscript{-1}) was paired with regular pacing at the identical rate (Figure 1). All pacing was applied using a biventricular lead approach (RV apex, LV lateral wall) to minimize the impact of pacing-induced dys-synchrony. Each pacing sequence spanned 160 beats (2 min at 80 min\textsuperscript{-1}, 1.3 min at 120 min\textsuperscript{-1}). The order of the pacing sequences was randomized to eliminate time-dependent effects. Data for each condition and mean rate were recorded twice and the results combined for each respective protocol.

**Data analysis**

Data were recorded by FLEXTIM II at a sampling frequency of 1000 Hz and filtered with a 0.5 Hz high-pass filter to remove the influence of respiration. Data were then edited to remove non-captured and ectopic beats and the beat just before and after ectopic events. Peak systolic and end-diastolic pressure were determined from the LV micromanometer, the latter defined as the pressure when $dP/dt$ reached 10% of $dP/dt_{max}$.
We also normalized dP/dt\text{max} to the instantaneous pressure (dP/dt\text{max}/IP) and end-diastolic volume (dP/dt\text{max}/EDV) to reduce load sensitivity. Central arterial systolic, diastolic, and digital mean pressure were obtained from the aortic micromanometer data. Calculations were performed beat-by-beat, and results averaged for each protocol and compared by paired Student’s t-test. The impact of mean heart rate was tested by comparing the differences between irregular vs. regular pacing data at 80 vs. 120 b.p.m. * mean rate. Significant level (two-sided) was adjusted by Bonferroni correction to P < 0.018 to account for the three paired comparisons with each parameter. Sample size was estimated from prior data indicating that a difference of >6% in key haemodynamic variables could be discerned with adequate power at n = 10. We stopped enrolment at n = 9 when our endpoints were clearly achieved.

For analysis of the beat-by-beat determinants of LV function, data from all patients were grouped per pacing protocol and used for the calculation of Spearman’s r. For quantification of non-linear relations between dP/dt\text{max} and end-diastolic volume with the ratio of preceding/preceding RR intervals (pRR/ppRR), data were normalized to individual mean regular rate data to enable patient results to be combined into a single plot. These data were then bin averaged over equally spaced ranges using an automated algorithm to simplify the plot display, and curve fit using a monoequational equation:

\[ y = C\left(1 - e^{-(R R_{\text{p}} - R R_{\text{p}})/t_{\text{r}}}\right) \]

where C = plateau amplitude, RR\text{p} = ratio of preceding/preceding RR interval, [pRR/ppRR], t\text{r} = refractory interval, and t = time constant of restitution.

This model is widely used for such force-interval relation analysis. The pRR/ppRR ratio was used as it normalized the RR interval of the beat just prior to the haemodynamic response to the beat preceding that. This determined whether the test beat RR interval (pRR) was shorter (pre-excitation) or longer (potentiated) than the preceding one (ppRR).

**Results**

All subjects completed the study protocol. The volume catheter signal was uninterpretable in three subjects due to low signal–noise ratio from marked chamber dilation and reduced ejection. This was identified at the time of study and volume data from these subjects were not analysed.

**Impact of heart rate irregularity on haemodynamics varies with mean rate**

Figure 2A displays example pressure–volume loops recorded during a period of either steady state or irregular rate pacing. Histograms showing the distribution of derived chamber function parameters [dP/dt\text{max}, dP/dt\text{min}, and LV end-diastolic pressure (LVEDP)] are displayed in Figure 2B. Function parameters followed Gaussian distributions and were broader with AFib-type stimulation as expected. Summary data based on these distributions are provided in Table 2. At 80 min\(^{-1}\) mean rate, dP/dt\text{max} did not change and dP/dt\text{max}/instantaneous pressure (IP) increased slightly (+6.3%, P = 0.004), while dP/dt\text{max}/LV end-diastolic volume (EDV) was not altered (P = 0.7) comparing irregular vs. steady-rate biventricular pacing.

In contrast, contractility was depressed by irregular vs. regular pacing at the faster (120 min\(^{-1}\)) mean rate (dP/dt\text{max}: −8.2%, P < 0.001; dP/dt\text{max}/IP: −12%, P = 0.007; dP/dt\text{max}/EDV: −5.5%, P = 0.1) (Figure 3). Diastolic function indexed by LVEDP and dP/dt\text{min} were also unaffected by rate irregularity at the normal rates, but increased by 26 and 21%, respectively (both P < 0.001) with irregular pacing at the faster rate. Systolic blood pressure was unchanged by rhythm regularity (at either mean heart rate), whereas mean and pulse pressure declined slightly with irregular stimulation at both rates, principally due to a greater incidence of non-ejecting beats (5.7% of the beats at 80 min\(^{-1}\); and 14.3% at 120 min\(^{-1}\)). Excluding non-ejecting beats eliminated this disparity in pulse pressure. Cardiac stroke volume and end-systolic and end-diastolic volumes were similar between regular and irregular rate pacing at both mean rates. Paired analysis confirmed a significant impact of mean heart rate on the haemodynamic influence of rate irregularity for dP/dt\text{max}, dP/dt\text{max}/IP, dP/dt\text{max}/EDV, dP/dt\text{min} and LVEDP, whereas the rate interaction on other parameters was not significant (Table 2).

**Determinants of ventricular performance during irregular rhythm**

The dP/dt\text{max} ratio positively correlated with the length of the preceding RR interval (pRR) at both mean heart rates (Spearman’s r = 0.41 and r = 0.68, both P < 0.001), and correlated more strongly with the pRR/ppRR ratio (r = 0.69 and r = 0.74, both P < 0.001). At the faster mean rate, the relation between contractility and pRR/ppRR ratio was steeper, indicating enhanced force–frequency dependence (Figure 4). Similarly, dP/dt\text{min} negatively correlated with pRR and pRR/ppRR ratios (r = −0.30 for each at both mean rates, P < 0.001). Enhanced contractility with a faster mean rate (positive force–frequency response) was present with regular but not with irregular pacing (P = 0.006).

Systolic function also depends upon net filling, yet the relation between LVEDP and dP/dt\text{max} was very weak at the 80 min\(^{-1}\) mean rate (r = 0.23, P < 0.001) and non-significant at 120 min\(^{-1}\). As shown in Figure 4, the dependence of LVEDP on the pRR/ppRR ratio was considerably less than on contractility. Furthermore, increasing the mean pacing rate influences the dependence of contractility but not preload on pRR/ppRR.

**Discussion**

This study demonstrates that rate regularization in patients with heart failure and AFib improves systolic and diastolic function when mean heart rate is elevated, but has negligible effects when the rate is in the normal range. We found that contractile function and relaxation, rather than net chamber filling, are more potently influenced by rate irregularity. These data suggest that patients with heart failure and AFib, but adequate mean rate control, are unlikely to benefit further from rate regularization. Targeted use of rate regularization at
higher frequencies—perhaps coupled to rate-triggered algorithms—may be beneficial.

Several prior studies in both animals and humans have assessed the effects of heart rate irregularity on cardiac function. In anaesthetized dogs, irregular LV apex pacing lowered cardiac output by 9% and produced mitral regurgitation when compared with regular pacing.\(^1\) In patients with AFib but generally preserved systolic function, irregular RV pacing resulted in 15% reduction of cardiac output and increased mean pulmonary wedge pressure when compared with regular RV pacing at the identical mean rate.\(^2\) This was also shown by Daoud et al.\(^3\) who found a 12% reduction in cardiac output at mean rates of either 80 or 120 min\(^{-1}\).

While these data would seem to counter the present findings, there are important differences that may...

Our finding that rate irregularity had a significant adverse impact on systolic function at the faster rate is supported by recent experimental data in a canine model of AFib in which haemodynamics were assessed invasively at different mean heart rates. The differences between AFib and regular pacing rate were less at slow invasively at different mean heart rates. The differences between AFib and regular pacing rate were less at slow in,
