Keywords: biomarker, ELISA, Tamm–Horsfall protein, uromodulin-associated kidney disease

ABSTRACT

Background. Uromodulin (Tamm–Horsfall protein) is the most abundant protein excreted in the urine under physiological conditions. It is exclusively produced in the kidney and secreted into the urine via proteolytic cleavage. The involvement of UMOD, the gene that encodes uromodulin, in rare autosomal dominant diseases, and its robust genome-wide association with the risk of chronic kidney disease suggest that the level of uromodulin in urine could represent a critical biomarker for kidney function. The structure of uromodulin is complex, with multiple disulfide bonds and typical domains of extracellular proteins.

Methods. Thus far, the conditions influencing stability and measurement of uromodulin in human urine have not been

systematically investigated, giving inconsistent results. In this study, we used a robust, in-house ELISA to characterize the conditions of sampling and storage necessary to provide a faithful dosage of uromodulin in the urine.

**Results.** The levels of uromodulin in human urine were significantly affected by centrifugation and vortexing, as well as by the conditions and duration of storage.

**Conclusions.** These results validate a simple, low-cost ELISA and document the optimal conditions of processing and storage for measuring uromodulin in human urine.

**INTRODUCTION**

Urinary biomarkers constitute an essential tool for the diagnosis, classification and prognosis of kidney diseases [1]. Recent evidence pointed at uromodulin (Tamm–Horsfall protein) as a potential urinary biomarker relevant for renal function, chronic kidney disease (CKD) and hypertension [2, 3]. Uromodulin is a 105 kDa glycoprotein with seven N-glycosylation sites and a high-mannose chain. The protein contains 616 amino acids including 48 cysteine residues that are all engaged in the formation of disulphide bonds. Uromodulin contains three epidermal growth factor-like domains and a zona pellucida formation of disulphide bonds. Uromodulin contains three epidermal growth factor-like domains and a zona pellucida domain found in many extracellular proteins, as well as a glycosylphosphatidylinositol-anchoring site [3]. Uromodulin is a kidney-specific protein that is exclusively synthesized in the epithelial cells lining the thick ascending limb (TAL) of Henle’s loop [4]. After proper trafficking and maturation in TAL-lining cells, uromodulin reaches the apical plasma membrane, to be cleaved and assembled in the urine as polymers forming a gel-like structure [5].

Uromodulin is produced at a very high rate in the TAL, and is by far the most abundant protein in normal urine (excretion: 50–100 mg/day) [6]. Functions attributed to uromodulin include protection against urinary tract infections; prevention of renal calculi formation by reducing aggregation of calcium crystals and influencing transport processes by regulating the activity of the sodium-potassium-chloride co-transporter (NKCC2) and/or the potassium channel ROMK [7, 8]. Interest for uromodulin was re-ignited when it was discovered that mutations in the UMOD gene that codes for uromodulin are responsible for a series of monogenic disorders (familial juvenile hyperuricaemia nephropathy, medullary cystic kidney disease type 2 or glomerulocystic kidney disease) all known as uromodulin-associated kidney diseases (UAKD) [3]. These disorders are characterized by severe tubulointerstitial damage, defective urinary concentration, hyperuricaemia and gout, and progressive renal failure [9]. The mutations often affect cysteine residues, resulting in conformational changes and intracellular aggregates of uromodulin. In turn, the secretion of the protein by the TAL cells is altered, resulting in a strong decrease in the urinary excretion of uromodulin [10–12]. Recently, a number of genome-wide association studies revealed that variants in the UMOD gene are associated with markers of renal function and risk of developing hypertension and CKD in the general population [13–15]. The association of uromodulin with both monogenic diseases and complex disorders such as CKD and hypertension provides a strong rationale for evaluating its urinary concentration as a biomarker for renal function and CKD.

The determination of uromodulin in the urine is hampered by its capacity to aggregate and the potential instability of such a complex protein. Documentation of sampling, processing and storage conditions is thus crucial for accurate uromodulin quantification. Despite the early characterization of antibodies specific for human uromodulin [16], the few reports on uromodulin dosage yielded conflicting results in terms of stability, storage conditions and processing of human urine [17–20]. Important points such as the potential influence of urine centrifugation or vortexing, acidification or alkalinization, treatment with protease inhibitors, or normalization for urinary creatinine remain unsolved. Furthermore, earlier immunoassays were often based on poorly documented anti-uromodulin antibodies. Considering the increasing interest for a determination of uromodulin in the urine, the need for a high-throughput assay, and the limited and contradictory information available, we developed and characterized a enzyme-linked immunosorbent assay (ELISA) for uromodulin and used this assay to investigate the stability of uromodulin under different treatment and storage conditions of human urine.

**MATERIALS AND METHODS**

**Urine sample collection, storage and handling**

Analyses were performed on second morning urine samples collected (mid-stream) in a sterile container from healthy volunteers aged 18–50 years, and processed within 2 h. This protocol was approved by the Ethical Committee of the Université Catholique de Louvain.

The influence of human urine sample processing on the determination of uromodulin (Figure 1) was tested after vortexing the sample for 10 s (Vortex-Genie 2; FAUST, Schaffhausen, Switzerland); centrifugation for 10 min at 3600 r.p.m. (Eppendorf Centrifuge 5430, Hamburg, Germany) at room temperature (i.e. standard protocol for urine processing and removing cells and debris [21]); treatment with protease inhibitors (Leupeptin 1 μmol/L; Sigma-Aldrich, St. Gallen, Switzerland; sodium azide 10 mmol/L); pH adjustment performed by drop titration with 1 N HCl (to pH 2.0) or with 1 N NaOH (to pH 8.0) using a Hanna HI 2211 pH meter; dilution using ultrapure deionized water (Destamat Bi 18E; QCS, Maintal, Germany) versus triton-EDTA (TEA) buffer (0.5% Triton X-100, 20 mM ethylenediaminetetraacetic acid (EDTA), pH 7.5). The effect of storage conditions was tested by comparing baseline levels with 1-week and 5-month storage at room temperature, +4°C and −20°C; 4- and 8-month storage at −80°C; five cycles of freezing–thawing (sample kept at −80°C for 48 h followed by thawing on ice). Different sample sets were used to evaluate the influence of the various processing conditions as described.

**Uromodulin ELISA**

The in-house ELISA for uromodulin is a colorimetric-based sandwich immunoassay using a sheep anti-human uromodulin antibody (Meridian Life Science, Memphis, TN, USA;
K90071C) as the capture antibody. This antibody gives a single arc when tested by immuno-electrophoresis against fresh urine. The primary antibody was a monoclonal anti-human uromodulin antibody (Cedarlane Laboratories, Burlington, NC, USA; CL 1032A) raised in mouse and validated in solid phase radioimmunoassay. The secondary antibody was a goat anti-mouse IgG (H + L) horseradish peroxidase conjugated (Bio-Rad, Cressier, Switzerland; 172.1011). The substrate was O-Phenylenediamine dihydrochloride (OPD) (10 mg/tablet) (Sigma-Aldrich). The OPD substrate solution was freshly prepared by dissolving a tablet in 25 mL of phosphate-citrate buffer [0.1 M citric acid monohydrate, 0.2 M Na2HPO4], pH 5.5. A volume of 5 µL 30% H2O2 was added to 25 mL of substrate solution. Human uromodulin (Millipore, Billerica, MA, USA) was used to establish the standard curve, with freshly prepared serial dilutions from the standard stock solution (100 µg/mL). Both the standard curve and a standard sample (uromodulin concentration 25 µg/mL) were systematically used for quality control (QC).

The determination of urinary uromodulin by ELISA was carried out as follows: a 96-well microtitre plate (NUNC MaxiSorp™; eBioscience, Vienna, Austria) was coated with 100 µL of 5 µg/mL capture antibody in coating buffer [500 mM H3BO3, 500 mM KCl, 345 mM NaOH, pH 9.0]. The plate covered with adhesive seal was incubated at 4°C overnight then washed three times with freshly prepared washing buffer [0.1% Tween 20 in 10 mM phosphate buffer saline (PBS) pH 7.2 (PBS–Tween 0.1%) using ImmunoWash 1575 Microplate Washer (Bio-Rad)]. Unoccupied sites on the plate were blocked with 100 µL blocking buffer [0.5% bovine serum albumin (BSA) in 10 mM PBS, pH 7.2] and incubated at 37°C for 1 h (rotation, 100 r.p.m.). The plate was then washed three times with washing buffer and placed upside-down on absorbent paper to remove residual buffer. One hundred microlitres of PBS–Tween 0.1% was dispensed in all wells. Urine samples were stabilized at room temperature then diluted 1:50 in ultra-pure deionized water, as preliminary testing revealed no significant difference versus dilution with TEA buffer (data not shown). A volume of 100 µL per well was distributed into the coated wells after vortexing. Standards and QC sample were run in duplicate, whereas each urine sample was tested in three different dilutions. Deionized water was used as blank. After 1 h incubation at 37°C, the plate was washed three times and placed on absorbent paper. One hundred microlitres of primary antibody diluted in PBS–Tween 0.1% (1 µg/mL) was dispensed in each well; the plate was incubated at 37°C for 1 h (rotation, 100 r.p.m.) then washed three times. The secondary antibody diluted 1:2000 in PBS–Tween 0.1% was added to the wells for 45 min at 37°C and the plate washed three times. Colour was developed by adding 100 µL of OPD substrate solution. The plate was incubated at room temperature in the dark for 1 min, and the reaction stopped by adding 50 µL of 2 M H2SO4 to each well. Optical density (Infinite M200Pro; Tecan, Grödig, Austria) was read at 492 nm and urinary uromodulin concentration was determined by referring to the standard curve. Uromodulin levels obtained using the in-house ELISA were compared with the commercial ELISA from MD Bioproduct (St. Paul, MN, USA; M036020), following the protocol given by the manufacturer. This test has been used in several studies [13, 22]. Urinary creatinine levels (normalization) were measured using the Synchron® System Creatinine Assay (Unicell DxC Synchron®; Beckman Coulter, Brea, CA, USA), following the manufacturer’s instructions.

Immunoblotting

Kidneys from Umod mice [23] were grounded in liquid nitrogen and homogenized as described previously [12]. The homogenate was centrifuged at 1000 g for 15 min at 4°C and the resulting supernatant at 100 000 g for 120 min at 4°C. The pellet was suspended in homogenization buffer before determination of protein concentration (Pierce BCA protein assay kit; Thermo Fischer Scientific, Rockford, IL, USA). Sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis for mouse and human samples was performed under reducing conditions. Samples (20 µg of mouse and human kidney...
extract; 2 µL of urine) were loaded after being mixed with Laemmli sample buffer and heated for 5 min at 95°C (kidney samples). Proteins were separated on 10% SDS gel and transferred to nitrocellulose membrane for western blotting. Membranes were blocked with 5% milk blot for 30 min at room temperature then incubated overnight at 4°C with either sheep or mouse anti-uromodulin antibodies (1:400 in 0.5% BSA blocking buffer). Secondary antibodies were goat anti-mouse horseradish peroxidase (HRP) conjugated (1:10 000) or polyclonal rabbit anti-sheep HRP conjugated (1:1000), for 1 h at room temperature. Antigen-antibody reaction was detected by using enhanced chemiluminescence (Immun-Star HRP, Bio-Rad) and light-sensitive film (GE Healthcare, Glattbrugg, Switzerland). The molecular weight was estimated by running the Precision Plus Protein™ All Blue standard (Bio-Rad).

### Deglycosylation and desialylation of uromodulin

Deglycosylation of uromodulin from human urine was carried out using peptide -N-Glycosidase F (PNGase F) (PNGase F P0704S; New England Biolabs, Ipswich, MA, USA) following the manufacturer's protocol, whereas desialylation was performed according the protocol described by Parsons et al. [24]. Briefly, uromodulin was precipitated from pooled human urine (1.5 L) following the protocol of Tamm and Horsfall [2], dialysed overnight at 4°C and then lyophilized (Virts, Kloten, Switzerland). Dry uromodulin was solubilized in 2.5 M acetic acid (10 mg/mL), heated for 3 h at 82°C, then washed three times with 15 mL PBS (pH 7.2) on Centricon (MWCO 30000) cartridge (Millipore). Of note, 1.5 µL of deglycosylated urine and 0.1 µL of desialylated uromodulin (versus 0.5 µL of untreated urine) were loaded on 10% acrylamide gel and analysed as described above.

### Immunohistochemistry

Colocalization of uromodulin with NKCC2 was carried out in cryosections of human and mouse kidney samples as previously described [10, 12]. Briefly, 5-µm-thick cryosections were blocked with 1% BSA/0.02% sodium azide-PBS for 30 min at room temperature, incubated for 2 h at room temperature with the sheep (1:400) or mouse (1:200) antibodies against human uromodulin, followed by washing and incubation with AlexaFluor633-conjugated donkey anti-sheep or goat anti-mouse (1:200) for 90 min at room temperature. Uromodulin-stained sections were then incubated with a polyclonal rabbit anti-NKCC2 antibody (Millipore; AB3562P; 1:100) for 3 h at room temperature, followed by washing and incubation with AlexaFluor488-conjugated goat anti-rabbit antibodies (1:200). Sections were viewed on a Leica SP5 confocal microscope.

### Surface plasmon resonance: Biacore

The interaction between uromodulin and the capture antibody was analysed by surface plasmon resonance, using a Biacore T100 system (GE Healthcare, Uppsala, Sweden). Chemicals were from Sigma unless otherwise noted. Binding experiments were performed in PBS buffer pH 7.4 containing 0.2% of Tween 20 at a flow rate of 30 µL/min at 25°C. Ultrapure and filtered water (‘MilliQ’; Millipore) was used for preparing all solutions. The carboxymethyl dextran chip (CMD500L™; XanTec bioanalytics, Düsseldorf, Germany) surface (1.2 mm² area) was cleaned before use by injecting seven times a 50 mM NaOH solution containing 1 M NaCl for 30 s at a flow rate of 5 µL/min. Surface binding is expressed in terms of changes in response units (RU) with 1 RU being ~1 pg/mm². Sheep polyclonal anti-uromodulin antibody (300 nM) in PBS–Twee was immobilized by amine coupling to the chip surface activated with aqueous solutions of 0.4 M 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide and 0.1 M N-hydroxysuccinimide for 300 s at 5 µL/min flow rate. For the determination of kinetic constants, a dilution series of four concentrations (19, 39, 78 and 156 nM) of uromodulin was injected using the T100 in multichannel mode. The reference channel used in parallel did not contain immobilized antibody, in order to detect background response and unspecific binding of analyte to the surface. Between two measurements, the surface was regenerated by injecting twice 10 mM glycine at pH 2 for 30 s, which completely removed uromodulin from the antibody. For data evaluation, the measured sensorgrams were referenced twice, first by subtracting the signal from the reference channel, and second by subtracting the signal obtained from injected pure buffer solution. Kinetic curves were evaluated using Biacore T100 Evaluation Software (v. 2.0.2). A global fit was performed using the entire concentration series. Rate constants for association and dissociation were calculated by taking a 1:1 binding model as a basis.

### Data analysis

Data were analysed using Statistical Package for Social Sciences (SPSS) version 19 (IBM Corp., Armonk, NY, USA). The Pearson correlation coefficient was used for correlation analysis, whereas analysis of variance (ANOVA) and paired t-test were used for comparisons between the groups. A Bland–Altman plot was used to evaluate agreement between uromodulin levels measured with the in-house ELISA and commercial kit. The level of significance was set to P < 0.05.

## Results

### Characterization of the antibodies against human uromodulin

The antibodies used for the in-house ELISA were characterized by immunoblotting and immunostaining (Figure 2). Immunoblot analysis of human urine and kidney samples in parallel with mouse kidney samples using the sheep polyclonal antibodies detected the uromodulin band at ~100 kDa in all samples except the Umod knock-out (KO) kidney sample. The uromodulin band was also detected in human urine and kidney samples using the mouse monoclonal antibody (Figure 2A, top panel). Both the polyclonal and monoclonal antibodies also appropriately identified the deglycosylated and desialylated forms of uromodulin (Figure 2A, lower panels).

Staining of human and mouse kidney tissue samples with the mouse monoclonal or the sheep polyclonal antibodies detected uromodulin in the TAL, where it colocalized with NKCC2 at the apical surface area (Figure 2B). Surface...
FIGURE 2: Characterization of anti-human uromodulin antibodies. (A) Western blot analysis (10% acrylamide gel) of human urine (2 µL), human kidney tissue (20 µg) and Umod knock-out (KO) and wild-type (WT) mouse kidney tissue (20 µg) using the sheep polyclonal or the mouse monoclonal antibodies against human uromodulin. A single band at ∼100 kDa is detected with both antibodies, and absent in the Umod KO mouse kidney (top panel). The changes in molecular mass resulting from deglycosylation (lower left panel) and desialylation (lower right panel) of uromodulin are evidenced by using both the polyclonal and monoclonal anti-uromodulin antibodies. Of note, 1.5 µL of deglycosylated urine and 0.1 µL of desialylated uromodulin (versus 0.5 µL of untreated urine) were loaded the gel. (B) Immunostaining of human cortical
plasmon resonance [25] was further used to characterize the uromodulin—antibody interaction (Figure 2C). As the isoelectric point of uromodulin (pI = 3.2) is too low for its immobilization to a carboxymethyl dextran surface, the capture sheep anti-uromodulin antibodies were immobilized at the surface of a sensor chip, and a dilution series of uromodulin was injected. For the interaction of immobilized sheep anti-uromodulin antibody with uromodulin, rate constants for association ($k_{on}$) and dissociation ($k_{off}$) of $4 \times 10^4$ M$^{-1}$ s$^{-1}$ and $4 \times 10^{-4}$ s$^{-1}$, respectively, were determined, giving a dissociation constant $K_D (=k_{off}/k_{on})$ of 10 nM. We also measured a strong binding response for the interaction of mouse anti-human uromodulin antibody to the sheep anti-uromodulin antibody—uromodulin complex. This situation is comparable with the conditions in ELISA (see below). Regeneration of the surface with 10 mM glycine at pH 2.0 removed both the antibody and uromodulin.

**Characteristics of the ELISA for uromodulin**

When tested against purified human uromodulin, the in-house ELISA for human uromodulin showed a sensitivity (minimum amount of analyte which can be accurately detected) of 2.8 ng/mL and a linearity (correlation between concentration and optical density) of 1.0 (Figure 3A). The inter- and intra-assay variabilities were determined at 3.28 and 5.46%, respectively. The assay had a detection range between 3.9 and 500 ng/mL. When compared with other assays, the in-house ELISA showed a wider range of measurement and lower intra- and inter-assay variability than commercially available routine kits (Table 1). There was a robust correlation ($r = 0.905$, $P < 0.001$) when comparing the in-house ELISA with the MD Bioproduct kit. The Bland–Altman plot showed that the mean difference between both methods was $-1.47 \mu$g/mL (95% CI, $-3.21$ to $0.27 \mu$g/mL) (Figure 3B).

**Influence of processing of urine samples**

Since uromodulin has a tendency to aggregate, we first investigated the potential influence of vortexing and centrifugation on the determination of uromodulin in human urine (Table 2). Comparison of fresh samples assayed before and after vortexing revealed a $>50\%$ increase in uromodulin levels (unindexed uromodulin: 5.02 ± 0.66 versus 11.03 ± 1.67 µg/mL, respectively, $P = 0.001$; indexed uromodulin: 10.84 ± 0.54 versus 15.90 ± 1.45 mg/g creatinine, respectively, $P = 0.001$, $n = 37$). Treating the urine samples with a usual centrifugation protocol (10 min, 3600 r.p.m.) also showed a significant decrease in unindexed (6.40 ± 0.63 versus 13.27 ± 1.18 µg/mL, respectively, $P < 0.001$) and indexed (9.97 ± 1.43 versus 15.66 ± 1.34 mg/g creatinine, respectively, $P < 0.001$, $n = 53$) uromodulin levels. Immunoblotting analyses (Figure 4) revealed that centrifugation induced the precipitation of uromodulin in the pellet of cell debris. In comparison with the uromodulin band detected in fresh, non-centrifuged urine samples, the signal was strongly attenuated in the centrifuged urine sample while becoming apparent in the resulting pellet.

Alkalization of fresh urine sample to pH 8.0 did not influence the determination of urinary uromodulin, when compared with untreated (mean pH 5.68 ± 0.19) samples (unindexed uromodulin: 19.25 ± 4.14 versus 20.60 ± 5.24 µg/mL, respectively, $P = 0.179$; indexed uromodulin: 17.56 ± 2.28 versus 18.34 ± 2.67 mg/g creatinine, respectively, $P = 0.260$, $n = 14$). Likewise, acidification of urine samples to pH 2.0 did not result in a significant difference between values from untreated (mean pH 6.15 ± 0.59) samples (unindexed uromodulin: 10.01 ± 2.25 versus 9.73 ± 2.07 µg/mL, respectively, $P = 0.621$; indexed uromodulin: 18.86 ± 8.26 versus 19.10 ± 8.55 mg/g creatinine, respectively, $P = 0.782$, $n = 8$).

**Influence of storage conditions**

In order to cast light on the influence of storage conditions on the stability of uromodulin, we compared values obtained in samples analysed at baseline and after 1-week or 5-month storage at room temperature, +4°C and −20°C. When compared with baseline, storage at either room temperature or 4°C or even −20°C was associated with decreased levels of both unindexed and indexed uromodulin (Table 3). Addition of protease inhibitors at the time of collection had some effect on the degradation of the samples conserved at −20°C, but not on those kept at +4°C. In any case, the addition of protease inhibitors was insufficient to prevent a significant decrease in the uromodulin levels when compared with baseline values. In contrast, 4-month storage at −80°C was not associated with significant changes in uromodulin levels in untreated samples. Further analyses revealed a slight but significant decrease after 8-month storage at −80°C (baseline uromodulin: 23.73 ± 1.57 µg/mL versus 8 months: 20.13 ± 1.17 µg/mL, $P = 0.023$, $n = 142$). Freezing–thawing cycles (from −80 to 0°C) showed no significant changes in the levels of urinary uromodulin when compared with baseline (Table 4).

**DISCUSSION**

Increasing evidence suggests that the level of uromodulin in urine could represent a useful biomarker for kidney function [3, 26]. In this study, we validated an efficient and cost-effective immunoassay and characterized the conditions of kidney sections (top row) using polyclonal sheep antibodies against human uromodulin (red), evidencing the apical staining in TAL profiles that are also positive for NKCC2 (green). A similar co-distribution between uromodulin (red) and NKCC2 (green) is observed in mouse kidney, using the polyclonal (middle row) or monoclonal (bottom row) anti-uromodulin antibodies. Scale bar: 10 µm, inset: 2× zoom. (C) Sensorgrams for the interaction of purified human uromodulin (19–156 nM) with the immobilized sheep anti-uromodulin antibody by surface plasmon resonance technique using the Biacore system. Uromodulin was injected at 0 for 300 s. Red lines are the result of a global fit. The constant of dissociation ($K_D$) was determined after evaluating the association ($k_{on}$) and dissociation ($k_{off}$) rate constants simultaneously using 1:1 kinetic binding model.
sampling and storage necessary to provide a faithful dosage of uromodulin in human urine. The urinary uromodulin levels were significantly affected by centrifugation and vortexing, as well as by the conditions and duration of storage.

To develop the in-house ELISA, we used commercially available anti-uromodulin antibodies and validated their specificity in human and mouse kidney and urine samples. Both antibodies evidenced the ~100 kDa band corresponding to uromodulin on immunoblot, either in native or deglycosylated/desialylated state. They also showed the typical distribution along with NKCC2 in the apical membrane of the TAL. We used plasmon surface resonance to determine the binding constant for interaction of the immobilized sheep anti-uromodulin antibody to uromodulin to 10 nM which is in the expected range for an antibody-protein interaction. The immunoassay standard curve showed linearity over a broad

S. Youhanna et al.
range of values, allowing the detection of uromodulin with high sensitivity and very low inter- and intra-assay variability. It must be noted that, in contrast with previous results based on immunoblotting [20], dilution of the samples with deionized water yielded similar results than with TEA buffer. All these features, combined with an excellent correlation with the most used commercial ELISA, substantiate the interest of our immunoassay with the advantage of low cost, wide range of detection and low variability.

Our analyses revealed a striking effect of vortexing and centrifugation on the determination of uromodulin in the urine. These two procedures yielded variations reaching 50% of the levels obtained on control, unprocessed samples (Table 2). These findings are clinically relevant, because low levels of urinary uromodulin have been suggested to be of diagnostic value in UAKD [3, 9–11]. The effect of vortexing confirms the importance of the aggregation of uromodulin molecules in the normal urine. Uromodulin is also known to cofractionate with exosomes [27], the recovery of which is increased by vortexing [28]. Uto et al. [18] previously suggested that uromodulin may be trapped in cell debris or aggregated with crystals after centrifugation protocols that are usual to remove contamination due to lysis or suspended cells [29]. Our data confirm these findings and show that centrifugation of urine may decrease the level of uromodulin by ~30%. Thawed urine samples should thus be vortexed but not centrifuged before assaying uromodulin.

The stability of uromodulin during different storage protocols is critical for analysing large, multicentric cohorts.

Previous studies based on small sample size yielded inconsistent conclusions about the influence of storage duration and temperature [17–20]. Furthermore, these studies did not take into account normalization for urinary creatinine, which is usual for kidney biomarkers [29, 30]. Our results, obtained on a large number of samples, reveal that short (1 week) and longer (5 months) storage at room temperature, 4 or −20°C causes a significant decrease in indexed urinary uromodulin levels, largely due to decreased uromodulin. In contrast, a 4-month storage at −80°C is associated with marginal, non-significant decrease in the unindexed and indexed values. Of note, the decrease in unindexed uromodulin levels becomes significant after an 8-month storage at −80°C. The fact that storage of untreated urine samples at room temperature, 4°C or −20°C significantly decreases the level of uromodulin substantiates the observations of Kobayashi and Fukuoka [20]. This effect is only partially attenuated with protease inhibitors, which show some effect for samples kept at −20°C—but insufficient to prevent a significant degradation. Taken together, these data confirm the fact that urine samples should be stored at −80°C and assayed within 3 months to give the most reliable measurements. Of note, up to five freezing–thawing cycles on ice did not affect the stability of uromodulin stored at −80°C.

Previous studies also reported inconsistent results in terms of treatments (detergents or TEA buffer, alkalinization) supposed to solubilize aggregates of uromodulin in urine [17–20, 31]. Some of these treatments may interfere with the binding of uromodulin to the ELISA capture antibody [18]. We verified here that dilution with deionized water gave similar results than with TEA, and that urine alkalinization (or acidification) had no effect on the determination of uromodulin. These data support the conclusion that dilution of the sample with water before the assay, combined with vortexing, is an efficient way of disaggregation [31].

In summary, these data indicate that reliable uromodulin measurements can be obtained from untreated urine samples, provided they are immediately stored at −80°C and assayed within 3 months, with vortexing and dilution with water to prevent aggregation. This methodology will be useful for high-throughput analyses of uromodulin and its validation as a biomarker for renal function and risk of CKD.

Table 2. The effect of sample processing (vortex and centrifugation) on the concentration of uromodulin in the urine

<table>
<thead>
<tr>

<td></td>
</tr>
</tbody>
</table>

Urine samples were vortexed for 10 s. Centrifugation was performed for 10 min at 3600 r.p.m. at room temperature. Two different sets of samples were used to test the influence of vortexing (n = 37) and centrifugation (n = 53).

</table>

PI, treatment with protease inhibitors (Leupeptin and sodium azide). Three different sets of urine samples were used to assess influence of storage after 1 week (n = 13), 4 months (n = 61) and 5 months (n = 10) versus baseline levels.

\(^{a}\)ANOVA.

*P < 0.05 storage condition versus baseline.

**P < 0.05 no versus protease inhibitors, paired t tests.
