ABSTRACT

Bacteria react to adverse environmental stimuli by clustering into organized communities called biofilms. A remarkably sophisticated control system based on the dinucleotide 3′–5′ cyclic diguanylic acid (c-di-GMP) is involved in deciding whether to form or abandon biofilms. The ability of c-di-GMP to form self-intercalated dimers is also thought to play a role in this complex regulation. A great advantage in the quest of elucidating the catalytic properties of the enzymes involved in c-di-GMP turnover (diguanylate cyclases and phosphodiesterases) would come from the availability of an experimental approach for in vitro quantification of c-di-GMP in real-time. Here, we show that c-di-GMP can be detected and quantified by circular dichroism (CD) spectroscopy in the low micromolar range. The method is based on the selective ability of manganese ions to induce formation of the intercalated dimer of the c-di-GMP dinucleotide in solution, which displays an intense sigmoidal CD spectrum in the near-ultraviolet region. This characteristic spectrum originates from the stacking interaction of the four mutually intercalated guanines, as it is absent in the other cyclic dinucleotide 3′–5′ cyclic adenilic acid (c-di-AMP). Thus, near-ultraviolet CD can be used to effectively quantify in real-time the activity of diguanylate cyclases and phosphodiesterases in solution.

INTRODUCTION

The bacterial signaling molecule 3′–5′ cyclic diguanylic acid (c-di-GMP) (Figure 1) has recently attracted growing interest because of its central role in modulation of several cellular processes, including biofilm formation and drug resistance (1–3). The intracellular levels of c-di-GMP are modulated by the opposite activity of diguanylate cyclases (DGCs), which catalyze its synthesis from two GTP molecules, and specific phosphodiesterases (PDEs), which hydrolyze it into linear 5′-phosphoguanylyl-(3′–5′)-guanosine (pGpG) or to two molecules of GMP. The central role of these enzymes in biofilm formation makes them an ideal target for the development of new anti-biofilm compounds. It is known that c-di-GMP displays a rich polymorphism in solution, and that the equilibrium among the monomeric, dimeric, tetrameric and octameric species is affected by the presence of metal ions (4–6). However, only the monomeric and dimeric forms (Figure 1) have been found under physiological conditions, whereas higher oligomer formation occurs only at mM concentration or in presence of additional aromatic intercalators (7,8). The monomer–dimer equilibrium is also likely to play a physiological role, allowing bacteria to sense and control different local c-di-GMP concentrations. Indeed PilZ receptors binding to c-di-GMP as a monomer or as an intercalated dimer have been reported (9–11). The dimeric form is also observed in complex with DGCs, bound to a non-competitive inhibitory site (12–14), whereas PDEs bind c-di-GMP as a monomer at the active site (15–17). Despite the great effort in understanding the molecular
that of the complex with magnesium, previously available manganese complex was also solved and compared with (range). The crystallographic structure of the c-di-GMP–
ganese ions to promote c-di-GMP dimerization, giving rise (Hellma) with a path length of 1 cm on a JASCO J-710
CD experiments were carried out using quartz cuvettes

in vitro detection and quantification of c-di-GMP
produced or degraded by DGCs and PDEs is still not
available for reliable real-time measurements. The direct
and indirect methods currently available for c-di-GMP
quantification in enzymatic reactions are summarized in
Table 1, together with the enzyme(s) whose kinetic activity
has been characterized to date using the various methods.
Here, we report the detection and quantification of c-di-GMP
in solution by circular dichroism (CD) spectroscopy, a technique routinely used in protein and nucleic acids
characterization. This method is based on the ability of manganese ions to promote c-di-GMP dimerization, giving rise
to an intense CD signal because of the hyperchromic effect
of the four stacked bases. The CD signal linearly depends on
c-di-GMP concentration (even in the low micromolar range). The crystallographic structure of the c-di-GMP–manganese complex was also solved and compared with that of the complex with magnesium, previously available
(36). The CD method presented here, which does not require
the addition of chromophores, can be easily applied to
measure the kinetics of enzymes involved in c-di-GMP
turnover (DGCs and PDEs) in real-time, as supported by
the results reported in this work on two model enzymes
(PleD and RocR). To allow a better comparative evaluation,
we have also highlighted similarities and differences of this
method with other techniques available to date. Given that
we are only starting to appreciate the extent to which DGCs
and PDEs domain-containing proteins are functionally
diversified in bacteria, the availability of a novel biochemical
method able to measure both the DGC and PDE activity in
detail can be strategic in the c-di-GMP field.

Basis of the c-di-GMP signaling pathways and the growing
number of groups working in this field, a method for
in vitro detection and quantification of c-di-GMP

Influence of metal ions on c-di-GMP

To verify the influence of metal ions on the c-di-GMP
dimer formation, samples containing 15 μM c-di-GMP
(Biolog) in 20 mM Tris, pH 8, and 100 mM NaCl were
analyzed in the presence of 2.5–10 mM of manganese and/or magnesium chloride. To obtain the calibration
curves, increasing concentrations of c-di-GMP (1, 5, 10,
15, 20, 25 and 30 μM) in 20 mM Tris, pH 8, 100 mM NaCl,
10 mM MgCl2, 1 mM BeCl2, 10 mM NaF and 2.5 mM
MnCl2 (reaction buffer of PleD) were analyzed. The
same profile is obtained in the absence of BeF2 (data not
shown). CD analysis was performed in duplicates at 10°C,
25°C and 37°C.

Analysis of manganese affinity for c-di-GMP

Increasing concentrations of MnCl2 (0.2–15 mM) were
added to a sample containing 15 μM c-di-GMP (Biolog)
in 50 mM Tris, pH 7.5, 150 mM NaCl and 10 mM MgCl2.
CD spectra were recorded at 10°C after allowing the samples to equilibrate for 10 min. A KD of 262 ± 36 μM
for the c-di-GMP-Mn2+ complex was calculated by fitting
the observed CD282 signal as a function of MnCl2
concentration.

CD spectra of other nucleotides

The CD spectra of 15 μM pGpG (Biolog), c-di-GMP,
GMP (Sigma Aldrich) and GTP (Amersham Bioscience)
and c-di-AMP (Biolog) were recorded in 50 mM Tris,
pH 8, 150 mM NaCl, 10 mM MgCl2 and 2.5 mM MnCl2.
The spectra vary slightly with buffer conditions. The concentration of stock solutions of GTP and GMP was
determined by measuring the absorption at 253 nm using
13 700 M⁻¹ cm⁻¹ and 13 300 M⁻¹ cm⁻¹ as molar extinction
coefficients.

Kinetic studies

To study the diguanylate cyclase activity of purified
Caulobacter crescentus PleD, a 0.5 μM enzyme solution
was incubated for 10 min at room temperature in
20 mM Tris, pH 8, 100 mM NaCl, 10 mM MgCl2. The
enzyme was then activated by adding 1 mM BeCl2 and
10 mM NaF and kept at room temperature for 30 min.
The diguanylate cyclase reaction was performed at 20°C
in the presence of 2.5 mM MnCl2 and was started by adding
100 μM GTP; the time course of the reaction was followed
by directly measuring the CD signal at 282 nm. In parallel,
the reaction was followed under the same experimental

Figure 1. Chemical structure of c-di-GMP and 3D structure of mono-
meric and dimeric c-di-GMP as observed in the active and inhibitory
site of PleD, respectively (PDB ID: 1w25) (14). The equilibrium in
solution of the two species is affected by the presence of monovalent
or divalent cations (4–6).
conditions, but aliquots were taken at different times (1, 3, 5, 10, 30 and 60 min); samples were boiled for 10 min to stop the enzymatic reaction, spun down and filtered to remove the precipitated protein. The samples were then analyzed both by CD spectroscopy at 20°C and by Reverse-Phase-HPLC as described earlier in the text. The experiment was performed in duplicate. PleD was purified as previously described by Wassmann et al. (25). The enzymatic activity of beryllium-activated PleD was found to be 20 nmol/min/mg, in good agreement with the value previously published (18,19).

To study the phosphodiesterase activity of Pseudomonas aeruginosa RocR, a 0.5 μM enzyme solution was incubated for 10 min at room temperature in 20 mM Tris, pH 8, 100 mM NaCl, 5 mM MgCl₂ and 2.5 mM MnCl₂. The reaction was performed at 20°C and was started by adding 30 μM c-di-GMP. The enzymatic reaction was followed in real-time at 282 nm. In parallel, aliquots were taken at different times (3, 5, 15, 30 and 45 min), and 100 mM CaCl₂ or 25 mM ethylenediaminetetraacetic acid, pH 6.0, was added to stop the enzymatic reaction; samples were boiled for 10 min, spun down and filtered to remove the precipitated protein. Samples were then analyzed by CD spectroscopy at 20°C and by Reverse-Phase-HPLC. The experiment was performed in duplicate. RocR was purified as previously described by De et al. (13). The turnover number of RocR was found to be 0.1 s⁻¹, somewhat slower than the value previously published (0.67 s⁻¹), in which the activity was measured by following the production of pGpG at 23°C in the presence of 25 mM MgCl₂ (30); this difference is not surprising given the different experimental conditions used in the present work (lower temperature and MgCl₂ concentration).

Titration of PleD with c-di-GMP

To study the binding of c-di-GMP to PleD, increasing concentrations of c-di-GMP were added to a sample containing 10 μM of PleD in 20 mM Tris, pH 8, 100 mM NaCl, 10 mM MgCl₂, 1 mM BeCl₂ and 10 mM NaF. CD spectra were taken at 25°C after equilibration of the system. The spectra of the samples containing 25, 30, 35 and 40 μM c-di-GMP were measured again after the addition of MnCl₂ to a final concentration of 2.5 mM. The order of addition of the three components in the mixture (i.e. PleD+c-di-GMP+Mn²⁺ or c-di-GMP+PleD+Mn²⁺ or c-di-GMP+Mn²⁺+PleD) did not change the final spectrum (data not shown). The experiment was performed in triplicate.

Crystallization, data collection and structure solution

Single crystals of [Mn(H₂O)₄(c-di-GMP)₂]²⁺ complex suitable for X-ray diffraction were obtained by hanging drop vapor diffusion method. The best diffracting crystals grew from drops of 6 μl, obtained by mixing 5 μl of c-di-GMP solution (c-di-GMP 4.3 mM; MnCl₂ 30 mM; cacodilate, pH 6.5, 50 mM) and 1 μl of reservoir solution (2-methyl-2,4-pentanediol 50% v/v; cacodilate, pH 6.5, 50 mM). A crystal (0.5 × 0.5 × 0.2 mm³) was mounted at room temperature on a Bruker-Nonius Kappa CCD diffractometer equipped with a graphite monochromatedMoKα radiation (λ = 0.71073 Å, CCD rotation images). The crystal was tetragonal with space group I₄₁ and unit cell parameters: a = b = 20.05, c = 39.55 Å. Semi-empirical absorption correction (SADABS) was applied. Fourier reflection pairs were not merged to consider anomalous scattering from manganese and phosphorous atoms. The structure was solved by direct methods [SIR97 package (37)] and refined by the full matrix least-squares method on F² against all independent measured reflections [SHELXL program of SHELXL97 package (38)].

All non-hydrogen atoms were refined anisotropically. The final refinement converged to an R-value of 0.0969, for reflection with 1 > 2σ(I). Twinning by merohedry [180° rotation about (1 1 0)] was detected and contemplated in the refinement (the calculated twinning fraction was 0.186). Crystal data and refinement details are summarized in Supplementary Table S1. CCDC 913765 contains the supplementary crystallographic data for this article. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (international) +44 1223/336 033.

RESULTS AND DISCUSSION

Formation of the complex between c-di-GMP and manganese

The method presented here is based on the specific CD signal displayed by the intercalated dimer of c-di-GMP and on the ability of manganese ions to promote dimerization of this cyclic dinucleotide. The CD profile of c-di-GMP shows two peaks in the absence of metal ions, one positive at 255 nm and one negative at 282 nm (Figure 2A), similarly to that of left-handed Z DNA and inverted relative to right handed DNA and RNA (5). A sigmoidal CD profile is obtained when two or more identical chromophores are in close proximity (39); in the case of c-di-GMP, which can form a stable dimer in solution, a strong hyperchromic effect is observed, as previously reported (5) because of the stacking of the four guanine rings. As divalent metal ions are known to shift the equilibrium towards the dimer (4,5), we have analyzed the c-di-GMP CD profile in the presence of increasing manganese concentrations, analyzed in 50 mM Tris–HCl, pH 7.5, 150 mM NaCl, at 10°C. Ninety-five per cent of signal saturation is observed at 2.5 mM MnCl₂ (i.e. K_D for c-di-GMP-Mn²⁺ complex formation of 262 ± 36 μM). The signal is corrected for the Mn²⁺-free signal.

Figure 2. Effect of manganese on the dichroic signal of c-di-GMP in solution. (A) Influence of divalent metal ions on c-di-GMP dimer formation analyzed in 50 mM Tris–HCl, pH 7.5, 150 mM NaCl, at 10°C. MnCl₂ and MgCl₂ were added to a final concentration of 2.5 and 10 mM, respectively. (B) CD spectra of c-di-GMP showing the increase in the intensity of the dimer-specific peaks in the presence of increasing manganese concentrations, analyzed in 50 mM Tris–HCl, pH 7.5, 150 mM NaCl, at 10°C. (Inset) Plot of the CD signal at 282 nm as function of Mn²⁺ concentration. Ninety-five per cent of signal saturation is observed at 2.5 mM MnCl₂ (i.e. K_D for c-di-GMP-Mn²⁺ complex formation of 262 ± 36 μM). The signal is corrected for the Mn²⁺-free signal.
complex between the intercalated dimer of c-di-GMP and the manganese hydrated cation. Titration of c-di-GMP with Mn$^{2+}$ shows that the CD signal at 282 nm reaches a plateau for Mn$^{2+}$ concentrations above 2.5 mM (Figure 2B, inset), suggesting that the complex is $>95\%$ populated above this threshold.

The different dichroic features of c-di-GMP in the presence of Mn$^{2+}$ and Mg$^{2+}$ were unexpected because of the similarity of many properties between the two cations. Only two structures of a c-di-GMP intercalated dimer were solved, in complex with Mg$^{2+}$ or Co$^{2+}$, respectively, both in the early 90s (36,40). We have solved the crystal structure of c-di-GMP in complex with Mn$^{2+}$ to establish whether this cation, compared with Mg$^{2+}$ (36), may induce any conformational change in the structural organization of the complex that could account for the different ability of the two divalent cations to populate the complex in solution. The crystal structure of the complex [Mn(H$_2$O)$_4$(c-di-GMP)$_2$]$_{2+}$, determined at 0.9 Å resolution, is shown in Figure 3 and further illustrated in Supplementary Figure S1, Supplementary Movie S1 and Supplementary Table S1.

The structure shows non-significant differences with respect to that of the c-di-GMP-Mg$^{2+}$ complex (36), indicating that the substitution of manganese with magnesium does not interfere with the assembly of the intercalated dimeric structure nor with the binding mode of the metal ion. On the basis of these data, it seems reasonable to assign the different effect of Mn$^{2+}$ and Mg$^{2+}$ on the dichroic spectra of c-di-GMP to the presence of d-electrons in Mn$^{2+}$, which contribute to the electrostatic interactions between the cation and guanine bases (41). This interpretation is in agreement with the order of nucleotide-binding ability of divalent cations (Mg$^{2+} < $ Co$^{2+} < $ Ni$^{2+} < $ Mn$^{2+} < $ Zn$^{2+} < $ Cd$^{2+} < $ Cu$^{2+}$) deduced by empirical studies in the late 60s (42) and with quantum chemical calculations, which suggest that the different action of Mg$^{2+}$ and Mn$^{2+}$ towards nucleobases derives from the greater polarization and charge-transfer effects in the Mn$^{2+}$ complexes (43,44). Finally, comparative studies of the guanine ligand-binding properties of Mn$^{2+}$, Zn$^{2+}$, Ni$^{2+}$ and Mg$^{2+}$ have demonstrated that the transition metals show higher affinity for the nucleobase N7. This could determine the stabilization of the complex in the presence of Mn$^{2+}$ (41). Accordingly, an enhancement of the CD signal similar to that observed in the presence of Mn$^{2+}$ was observed also in the presence of zinc and nickel divalent cations (data not shown).

The formation of the c-di-GMP-Mn$^{2+}$ complex occurs rapidly, within 5 min at 10°C and within the mixing time at 25°C (data not shown). In the presence of 2.5 mM Mn$^{2+}$, the CD signal shows a linear dependence on c-di-GMP concentration; this linearity is maintained at the different temperatures analyzed (10°C, 25°C and 37°C) (Figure 4). The CD signal of the samples is stable for at least 4 h in the temperature range needed for enzymatic reactions (10°C–37°C) and is also reproducible after a 12 h storage at 4°C (data not shown), making this method adaptable to different protocols (i.e. from real-time detection to multiple analysis of many stored samples). The intense CD signature of the intercalated dimer is specific, thus c-di-GMP can be detected and quantified (even in the low micromolar range) in the presence of all the other nucleotides involved in c-di-GMP turnover. GTP and GMP are spectroscopically silent in the near-ultraviolet region, whereas pGpG displays a CD spectrum with a single band at 255 nm that possibly originates from the coupling of the two guanines, which are in close proximity (Figure 5). However, as it does not significantly contribute at 282 nm, the presence of pGpG does not hamper the quantification of c-di-GMP at 282 nm (Figure 5).

To assign the spectroscopic signature seen by CD to the stacking of the guanine bases, we have also measured the spectrum of another dinucleotide, i.e. 3′–5′ cyclic diadenilic acid (c-di-AMP); as shown in Figure 5, this dinucleotide shows a much lower intensity and a different profile in the presence of Mn ions with respect to c-di-GMP. The observation that c-di-AMP does not show the same spectroscopic signature of c-di-GMP strongly suggests that the sigmoidal CD signal arises from the stacking of the guanine bases. A comparison of the chemical structure of c-di-GMP and c-di-AMP highlights that the difference in the substituents in position N1 and the absence of the carbonyl group in the purine ring of c-di-AMP may disfavor the formation of a stacked dimer by c-di-AMP (see Supplementary Figure S2).

Probing the enzymatic activity of DGCs and PDEs

The CD method described here allows measuring c-di-GMP concentration in the working range typical of DGCs and PDEs enzymes. We have used the CD analysis to measure the enzymatic activity of two reference enzymes, i.e. PleD, a well characterized DGC from C. crescentus and RocR from P. aeruginosa, an EAL-type PDE (18,30).

The time course of the reactions catalyzed by these two enzymes was measured in real-time at 282 nm as shown in Figure 6 (panels A and B, respectively). The reaction rates were found to be in good agreement with the published values (18,19,30) (see ‘Materials and Methods’ section). As a control, the time course was also measured by extracting the nucleotides from aliquots of the reaction mixture taken at given times; these aliquots were then analyzed in parallel both by CD spectroscopy and by reverse-phase HPLC chromatography, the most common method to quantify c-di-GMP (see also Table 1) (45). The results obtained by CD analysis (point measurements) are fully consistent with data obtained by reverse-phase HPLC. The comparison of the kinetics as followed by real-time measurements with that obtained by point measurements (see Figure 6) clearly shows (more evidently in the case of RocR) that the real-time approach is an absolute requirement for an accurate determination of the time course of the reaction. The time course of the reaction of RocR was also measured in the absence of Mn$^{2+}$ (with Mg$^{2+}$ ions alone), and no difference was observed in the kinetic parameters (data not shown), suggesting that the real-time measurement can be carried out,
if needed, also in the presence of Mg²⁺ ions alone (using a consistent calibration curve).

Interestingly, we have also observed that, in the presence of the diguanylate cyclase PleD, the CD signal of c-di-GMP increases even in absence of manganese in the buffer (Figure 7, black circles). This is because of c-di-GMP binding to the enzyme inhibitory site as an intercalated dimer (14) with a similar structure of the c-di-GMP–Mn²⁺ complex (Figure 3). Accordingly, titrating PleD with c-di-GMP, the CD signal increases linearly with c-di-GMP concentration until all the inhibitory sites of PleD are saturated (i.e. a PleD:c-di-GMP binding stoichiometry of 1:2) (Figure 7). Further addition of c-di-GMP does not correspond to a significant increase of the signal given that, in the absence of free binding sites, c-di-GMP is prevalently monomeric. Addition of manganese to the solution results in a further increase in the intensity of the signal, which indicates a shift of the equilibrium of free c-di-GMP towards the dimeric form (Figure 7, blue triangles). This result confirms that a sigmoidal CD spectra peaking at 255 and 282 nm can be regarded as the spectroscopic fingerprint of the intercalated dimer.

CONCLUSIONS

The method presented here is based on the specific CD signal displayed by the intercalated dimer of c-di-GMP and on the ability of manganese ions to promote dimerization of this cyclic dinucleotide. We have observed that c-di-GMP displays a sigmoidal CD signature, related to the formation of an intercalated dimer, which is enhanced in the presence of Mn²⁺, but not Mg²⁺ ions. The crystallographic structure of the complex is further illustrated in Supplementary Figure S1 and Supplementary Movie S1.
that the two divalent cations display a different ability to populate the complex in solution. The present method can be used to measure the enzymatic rate of c-di-GMP production and degradation, as shown by the real-time measurements carried out on two reference enzymes, i.e. PleD diguanylate cyclase and RocR phosphodiesterase. The CD signal of c-di-GMP at 282 nm is specific of the dimeric form of the molecule; other nucleotides, such as GTP, pGpG or GMP, which are present during the reaction of diguanylate cyclases or phosphodiesterases, do not show the same signal. Moreover, the observation that the adenine dinucleotide c-di-AMP does not have the same spectroscopic signature suggests that the sigmoidal CD signal can be assigned to the stacking of the guanine bases.

Comparison of the distinctive features of the present method with those of the other methods available to measure enzymatic activities (as summarized in Table 1) underlines that this method is effective to measure steady-state kinetics of both DGCs and PDEs in real-time. As shown in Table 1, the kinetic properties of few enzymes have been studied to date with the methods already available; on the other hand, it is clear that a deep understanding of the mechanism controlling the turnover of c-di-GMP requires the biochemistry of its synthesis and degradation to be fully elucidated. A clear advantage of the approach presented here is that it allows to detect and to quantify c-di-GMP directly, without the need of additional chromophores, biosensors or dyes, and it does not require time-consuming sample preparation. In common with most methods, the sensitivity of the CD analysis lies in the micromolar range of c-di-GMP concentrations (Table 1). As far as real-time measurements are concerned, only the indirect EnzCheck method is suited to measure the time course of DGCs in real-time, but this method cannot be applied to PDEs; on the other hand, the activity of PDEs can be followed using the fluorescent MANT-c-di-GMP derivative as proposed by Sharma et al. (35).

In our opinion, the present experimental approach also opens novel scenarios and attractive possibilities in the field of c-di-GMP enzymes. The method will allow to conceive pre-steady state kinetic experiments, to date unexplored for these enzymes, but of crucial value to determine the reaction mechanism of both DGCs and PDEs. A detailed knowledge of the mechanistic details of these reactions is a necessary pre-requisite to design and to validate effective inhibitors that could be used as antimicrobial agents able to modulate c-di-GMP levels and to interfere with the formation of biofilms or with development of specific (antibiotic-resistant) phenotypes, such

Figure 6. Time course of the reaction catalyzed by the diguanylate cyclase PleD (Panel A) and by the phosphodiesterase RocR (Panel B) as monitored in real-time by following the CD signal at 282 nm at 20°C (continuous line). As a control, the concentration of c-di-GMP in individual samples taken at given times during the reaction was determined separately by CD spectroscopy (black circles) and reverse-phase HPLC (black squares). The diguanylate cyclase activity of PleD (0.5 μM) was monitored using 100 μM GTP (Panel A) in 20 mM Tris, pH 8, 100 mM NaCl, 10 mM MgCl₂, 2.5 mM MnCl₂, 1 mM BeCl₂ and 10 mM NaF. The phosphodiesterase activity of RocR (0.5 μM) was monitored using 30 μM c-di-GMP (Panel B) in 20 mM Tris, pH 8, 100 mM NaCl, 5 mM MgCl₂ and 2.5 mM MnCl₂. All assays were performed in duplicate.

Figure 7. Plot of the CD signal at 282 nm of samples containing increasing amounts of c-di-GMP in the presence of 10 μM PleD (monomer) (circles) or 2.5 mM MnCl₂ (squares). Addition of 2.5 mM MnCl₂ to the samples containing 25, 30, 35 and 40 μM c-di-GMP and 10 μM PleD yields the same CD signal (triangles) of the manganese-alone samples. Experimental conditions were as follows: 20 mM Tris–HCl, pH 8, 100 mM NaCl, 10 mM MgCl₂, 1 mM BeCl₂ and 10 mM NaF. The assays were performed in triplicate.
as those found in persister cells (46). Moreover, the experimental approach presented here might be used to explore the interplay of DGCs and PDEs in controlling c-di-GMP levels by allowing to measure the activity of these enzymes not only individually but also in combination in the same reaction mixture; this may provide quantitative evaluation of the interaction of proteins putatively involved in the same signaling pathway. As suggested by the recent evaluation of the different phenotypic output of the activity of the DGCs in *Vibrio cholerae*, the mechanism and rate whereby each individual DGC produces c-di-GMP and/or is regulated determine the stringent biological specificity of c-di-GMP signaling in the cell (47).
