ABSTRACT

Most of the factors involved in translation (tRNA, rRNA and proteins) are subject to post-transcriptional and post-translational modifications, which participate in the fine-tuning and tight control of ribosome and protein synthesis processes. In eukaryotes, Trm112 acts as an obligate activating platform for at least four methyltransferases (MTase) involved in the modification of 18S rRNA (Bud23), tRNA (Trm9 and Trm11) and translation termination factor eRF1 (Mtq2). Trm112 is then at a nexus between ribosome synthesis and function. Here, we present a structure-function analysis of the Trm9-Trm112 complex, which is involved in the modification of 5-methoxycarbonylmethyluridine (mcm5U) into 5-carboxymethyluridine derivatives (xcm5U) in 11 of those tRNAs (4). Among these modifications, 5-methoxycarbonylmethyl-(2-thio)uridine (mcm5U and mcm5s2U) were shown to enhance accurate and efficient translation and codon pairing (5).

The synthesis of cm5U(34) is very complex and requires at least 15 proteins in S. cerevisiae. Most of these proteins are involved in the first step of the reaction, i.e. addition of a carboxymethyl group at position 5 of the uracil to form cm5U (6). The enzyme catalyzing this reaction is the Elongator complex composed by six subunits (Elp1–6) (7). This complex consists of two sub-complexes: a core complex Elp1–2–3 where Elp3 is the catalytic subunit endowed with acetyltransferase activity and the Elp4–5–6 complex, an hexameric ATPase regulating tRNA dissociation from the Elongator complex (8). The other factors (Kti11–14, Sit4, Sap185 and Sap190) seem to be involved in the regulation of the Elongator complex (9). The last step in the synthesis of this modification requires the methylation of cm5U to form cm5s2U by the Trm9 methyltransferase (MTase) (10). This protein belongs to the class I-S-adenosyl-L-methionine (SAM)-dependent MTase family and is active as a complex with Trm112 (11). The deletion of the gene encoding any of these 15 yeast proteins results in zymocin resistance phenotype (7). Indeed, zymocin, a toxin secreted by K. lactis, exclusively cleaves the tRNA anticodon wobble position and hence promotes translational fidelity. We also compare the known crystal structures of various Trm112-MTase complexes, highlighting the structural plasticity allowing Trm112 to interact through a very similar mode with its MTase partners, although those share less than 20% sequence identity.

INTRODUCTION

The tRNAs play a central role in protein synthesis by bringing the amino acid corresponding to the mRNA codon present in the ribosomal A-site to the ribosomal peptidyl transferase center (PTC) during the elongation step of the translation process. Post-transcriptional maturation steps are essential for tRNA function. In particular, around 100 nucleoside modifications have been described for tRNAs (1) and were shown to mostly ensure either correct tRNA folding (2) or efficient and accurate decoding (3). Position 34 from the tRNA anticodon loop (also known as wobble) is frequently heavily modified, ensuring translational fidelity but also the recognition of several codons by a single tRNA molecule. In S. cerevisiae, 13 out of 42 tRNAs have a uridine at position 34 (U34), which is modified into 5-carboxymethyluridine derivatives (xcm5U) in 11 of those tRNAs (4). Among these modifications, 5-methoxycarbonylmethyl-(2-thio)uridine (mcm5U and mcm5s2U) were shown to enhance accurate and efficient translation and codon pairing (5).
plexes are involved in processes related to protein synthesis. Similarly to Trm9-Trm112, the Trm11-Trm112 complex methylates many tRNAs in yeast at guanosine 10 to form 2-methylguanosine (m2G10) and hence is involved in translational elongation (12). The Met2-Trm112 complex methylates translation termination factor eRF1 on the amide group of the glutamine side chain from the universally conserved GGQ motif, which enters into the PTC and triggers the release of newly synthesized proteins (13). The Bud23-Trm112 complex is implicated in the synthesis of the small ribosomal subunit by catalyzing the N1'-methylation of guanosine 1575 of 18S rRNA (14,15). Finally, Trm112 is important for synthesis of the large ribosomal subunit by an unknown mechanism (16). The Trm9-Trm112 complex catalyzed tRNA modification enhances decoding of AGA, CAA, GAA and, to a lesser extent, AGG codons (17). Hence, it favors the translation of transcripts specifically enriched in these codons such as those coding for the DNA damage response key proteins Rnr1 and Rrn3 (18). In S. cerevisiae, the deletion of the TRM9 gene results in increased sensitivity of the cell to DNA alkylation agent methyl methanesulfonate (MMS) and in delayed G1 to S phase transition after MMS treatment. Furthermore, tRNA hypomodification following Trm9 inactivation results in translational infidelity and triggers the activation of protein stress response pathways (19). Altogether, this indicates a connection between tRNA modification, regulatory networks, and stress response pathways (19). Interestingly, ABH8 silencing renders cells sensitive to MMS treatment (20), while the loss of ABH8 proteins represents potent targets for the development of new anti-cancer drugs.

Here, we describe the crystal structure of the Trm9-Trm112 complex from Yarrowia lipolytica as well as in vivo and in vitro functional studies of S. cerevisiae enzyme with the aim of analyzing the mechanism of action of this protein. From the comparison of the various known crystal structures of Trm112-MTase complexes, we also unravel the molecular plasticity allowing Trm112 to interact with its various MTase partners, which share less than 20% sequence identity.

**MATERIALS AND METHODS**

**Yeast strains, media and growth conditions**

Saccharomyces cerevisiae strain YPH499 (Agilent technologies) was used as the wild-type host for all yeast genetic manipulations. Kluyveromyces lactis AWJ137 and NK40 strains were used as source of zymocin and control strain, respectively, in zymocin killer eclipse assay and killer liquid assay (25). Cultures were performed at 30°C in standard rich medium YEPD (1% yeast extract, 2% peptone, 2% dextrose) or selective minimal media (SD) with 2% dextrose or galactose. Yeast was transformed by the lithium acetate method as previously described (26). For selection, YEPD was supplemented with gentamicin (200 μg/ml) and SD minus uracil or tryptophan was prepared.

**Yeast strains construction**

For clone selection, three steps were systematically considered: growth on a selective medium, polymerase chain reaction (PCR) screening and DNA sequencing. For point mutation strain selection, the presence of the mutation was also investigated by restriction fragment length polymorphism prior to DNA sequencing.

Ytrm9 point mutant strains were generated using genomic DNA from strain YDL201 (YPH499 TRM9::kanMX6) as DNA template and the suitable Ftmr9/R1-trm9 set of primers for initial cassette amplification (27) and the technique already described (28) (Supplementary Tables S2 and S3).

Clones expressing wild-type or mutant Trm9–13Myc were obtained from transformation of the appropriate strain (encoding wild-type or mutant Trm9) with PCR product amplified from pFA6a-13Myc-TRP1 plasmid as a template using F2-TRm9/R1-trm9 primer set (27).

The trm9Δ::URA3 strain was obtained by transforming wild-type strain with PCR product amplified from plasmid pESC-URA (Agilent Technologies) using F1-URA-trm9/R1-URA-trm9 primer set. Clones expressing Yftrm9 or Yftrm9N38 were obtained from a 5-FOA selection after transformation of trm9Δ::URA3 strain with PCR product amplified from Yarrowia lipolytica genomic DNA as a template using respectively Ftrm9::YLTRM9 or Ftrm9::YLTRM9N38 / Rtrm9::YITRM9 primer sets (Supplementary Table S3).

**Zymocin killer eclipse assay**

5 μl suspension of the yeast cells to test (OD600nm = 0.5) were spotted on YEPD plate and air-dried. Next, using the tip of a toothpick, K. lactis AWJ137 and NK40 cells were placed onto the edge of the yeast spot. Plate was incubated at 30°C for 1–2 days. Sensitivity or resistance to zymocin was revealed by the presence or absence of a halo zone around AWJ137 colony.

**Zymocin liquid killer assay**

Filtered-sterile supernatants from overnight culture of K. lactis AWJ137 and NK40 were used as source of zymocin...
and as a control, respectively. Serial dilutions of the supernatants (from $10^{-4}$ to $10^{-6}$) were prepared in fresh selective SD media with galactose as carbon source. 5 ml sample of each dilution was inoculated at OD$_{600nm}$ of 0.1 with yeast strain to be tested. Cultures were incubated for 20 h at 30°C. Growth was calculated as the ratio between the OD$_{600nm}$ read for the $10^{-1}$ and $10^{-4}$ dilutions. The 100% sensitivity to zymocin was obtained from the wild-type strain.

### Cloning expression and purification

A DNA sequence optimized for heterologous expression in E. coli was designed to encode YfTrm112 (UniProtKB entry: Q6C4P5) and YfTrm9 with a C-terminus His$_6$-tag (UniProtKB entry: Q6C999). This fragment was obtained by *de novo* gene synthesis (GenScript Corporation, Piscataway, NJ, USA) and was further subcloned into pET21a between NdeI and XhoI sites. Two truncated forms of YfTrm9 (YfTrm9N19 and YfTrm9N38 encompassing residues 19–324 and 38–324, respectively) were cloned in the same operon (Supplementary Tables S4 and S5). These complexes were expressed in *E. coli* BL21 (DE3) Gold (Novagen) in 800 ml autoinducing media (29) containing 10 μM ZnCl$_2$ and 100 μg/ml ampicillin, 5 h at 37°C and 15 h at 15°C.

Genes encoding wild-type ScTrm9 and ScTrm112 were amplified from *S. cerevisiae* S288C genomic DNA and cloned into a modified pET28a and a pACYCDUET-1 plasmids, respectively (Supplementary Tables S4 and S5). Genes encoding ScTrm9 mutants were amplified from the genomic DNA isolated from YPH499 mutated strains and then cloned into pET21a vector using NdeI and NotI restriction sites and introducing a C-terminal His$_6$-tag (Supplementary Table S4 and S5). The expression of the Sc-Trm9-Trm112 complexes was done in *E. coli* BL21 (DE3) Gold strain (Novagen) co-transformed with the two vectors and cultured in 1 l of 2YT medium containing 10 μM ZnCl$_2$, 25 μg/ml chloramphenicol and 100 μg/ml ampicillin. Cultures were done at 37°C until OD$_{600nm}$ reached 0.5–0.6, they were then shifted to 20°C and protein production was induced overnight with IPTG (final concentration of 0.5mM).

Bacteria were harvested and resuspended in 30 ml buffer A (20mM Tris-HCl pH7.5, 200mM NaCl, 5mM β-mercaptoethanol, 10μM ZnCl$_2$) and stored at −20°C. Cells were lysed by sonication and the soluble fraction was cleared by centrifugation (15 000g for 30 min at 4°C). All His$_6$-tagged complexes were purified by Ni-NTA chromatography (QIAGEN Inc.), followed by an ion-exchange chromatography (5 ml Heparkin column for Sc complexes and Yf full length complex and 5 ml MonoQ column for the Yf truncated forms (GE Healthcare)). The last purification step was performed on a Superdex 75 16/60 size-exclusion chromatography column (GE Healthcare) in buffer A.

### Crystallization and structure solution

Crystals were grown after 3–4 days at 19°C from a mixture of YfTrm9N38-Trm112 complex (10 mg/ml) with an equal volume of the crystallization solution containing 100mM tri-sodium citrate, 20% polyethylene glycol 4000 (PEG4K), 20% 2-propanol. Crystals were cryoprotected by transfer into the crystallization solution supplemented with 15 then 30% v/v ethylene glycol and then flash-frozen in liquid nitrogen. The data sets were collected at 100 K on Proxima-1 beam line (SOLEIL, St Aubin, France). The structure was solved by Zn-MAD (Multiple Anomalous Dispersion) using data sets collected at three wavelengths corresponding to inflexion, peak and remote of Zn-edge (see Table 1 for statistics). Data were processed with XDS (30) and scaled using XSCALE. The space group was I432 ($a = b = c = 176.2$ Å) with one heterodimer per asymmetric unit, corresponding to a solvent content of 56.4%. As expected from the presence of one Trm112 protein in the asymmetric unit, one Zn atom could be located by the HYSS submodule of the PHENIX package in the 50–3 Å resolution range (31). Refinement of the Zn atom coordinates, phasing and density modification were performed with SHARP program using the 50–3 Å resolution range (32). The ScTrm112 crystal structure (13) was positioned into the experimental density maps by molecular replacement using the MOLREP program (33) and then modified to match with the YfTrm112 sequence. The Trm9 model was built into these maps using the COOT molecular modeling program (34). Iterative cycles of manual model rebuilding using COOT followed by refinement with PHENIX led to an almost complete model, which was then completed and refined using a higher resolution data set (2.5 Å) to yield the final model (final R and R$_{free}$ values of 19.9% and 24.2%, respectively). The statistics for data collection and refinement are summarized in Table 1. The final model contains residues 1–124 from Trm112, residues 39–160 and 172–233 from Trm9, a zinc atom and 91 water molecules. According to PROCHECK (35), in this final model, 87% and 13% of the residues are in the most favored and in the allowed regions of the Ramachandran diagram, respectively. Due to the absence of electron density, the following regions are absent from the final model: residues 125–130 from Trm112 and 38, 161–171, 234 and the His$_6$ tag from Trm9.

### Enzymatic assay

For enzymatic assays, total tRNAs were purified from *S. cerevisiae* trm9Δ and epl1Δ strains (epl1Δ strain is a kind gift from Dr. B. Seraphin, IGBMC, France) using mostly the protocol described in Chen et al. (36). Yeast cells were grown in YEPD medium at 30°C until cell density reached 1 to 2×10$^7$ cells/ml. Cells were washed with water and harvested. The pellet was resuspended in one pellet volume of 0.9% NaCl then 2 volumes of phenol were added. The mixture was incubated on a rotating wheel for 30 min at room temperature. One volume of chloroform was added and the mixture was shaken for 15 min and then centrifuged for 20 min at 13000 rpm at 4°C. Aqueous phase was precipitated by 2.5 volumes of ethanol and 0.1 volume of 20% potassium acetate and washed with cold ethanol 95%. In order to remove bound amino acids, the precipitate was resuspended in 1.5 ml of 2 M Tris-HCl pH 8 (for 10 g of cells) and incubated for 90 min at 37°C. After ethanol precipitation, the pellet was resuspended in 3.4 ml of 2 M lithium acetate, 0.1 M potassium acetate pH 5 (for 10 g of cells) to remove ribosomal RNAs as described previously (37). The mix was shaken for 20 min at 4°C and centrifuged at 8000g for 20
min at 4°C. The pellet was extracted a second time with 1.7 ml of 2 M lithium acetate, 0.1 M potassium acetate pH 5. The pool of supernatants was dialyzed against 10 μM magnesium acetate during 2.5 h. The tRNAs were resuspended in 1 mM Tris pH 7.5, 10 mM magnesium acetate following ethanol precipitation.

The methyltransferase assay was performed in a final volume of 50 μl containing 50 mM phosphate buffer pH 7.5, 0.1 mM EDTA, 10 mM MgCl₂, 10 mM NH₄Cl, 0.1 mg/ml Bovine Serum Albumin, 10 μM of total tRNAs (75 pmol) puriﬁed from trm9Δ strain to the mixture. The samples were incubated at 37°C and aliquots were withdrawn at different time points. The reaction was stopped by precipitation with cold trichloroacetic acid (5%), followed by filtration on Whatman GF/C filters. The [3H]incorporation was measured using a Beckman Coulter LS6500 scintillation counter. For the pH dependence enzymatic assays, phosphate buffer pH 7.5 was replaced by other phosphate buffers ranging from pH 5–8. All reactions were performed in triplicates. The initial velocities (V₀) were calculated using the equation C_tRNA = V₀(1 - exp(-nt))/n where C_tRNA is the concentration of methylated tRNA, t, the time in minutes, V₀ the initial enzyme cycling velocity and n the relaxation constant of V₀ by fitting the experimental spots with the software ORIGIN according to Cao et al. (38).

Steady-state kinetics analyses were performed by using various tRNA (from 0.1 to 1.5 μM) or SAM (from 1 to 20 μM) concentrations. The initial rate calculated for each tRNA or SAM concentration was plotted as a function of time in minutes.

The equilibrium dialysis set up consists of two chambers separated by a 3 kDa-cut off dialysis membrane. The experiment was performed in 100 mM Tris-HCl pH 7.5, 0.1 mM EDTA, 10 mM MgCl₂, 10 mM NH₄Cl. Initially, the ligand chamber contains 100 μM SAM (containing 0.87 Ci/mmoll of [3H]-SAM, Perkin Elmer) and the protein chamber 120 μM of Trm9-Trm112 complex. After 3 h rotation at 4°C, the SAM content of chambers is determined using a Beckman Coulter LS6500 scintillation counter.

Co-IP and western blot

The preparation of the soluble protein extracts and the co-immunoprecipitation assays were performed as previously described (26). Probing was performed using either mouse 9E10 anti-myc (Santa Cruz Biotechnology) or polyclonal rabbit anti-Trm112 antibodies (Agrobio) as primary antibody (1/5000 dilution). Sheep anti-mouse or sheep anti-rabbit HRP-conjugated IgG were used as secondary antibody (1/5000, GE Healthcare).

Generation of YtTrm9N20-Trm112 model

Residues 20–39 from YtTrm9, which are missing in the crystal structure of YtTrm9N38-Trm112 complex, were modeled by superimposing the crystal structure of RPA2492, the closest structural YtTrm9 homologue (PDB code: 3E23), onto our structure. The SAM substrate and backbone atoms from residues 8–27 (corresponding to residues 20–39 from YtTrm9) were retained from the crystal structure.

### Equilibrium dialysis

The equilibrium dialysis set up consists of two chambers separated by a 3 kDa-cut off dialysis membrane. The experiment was performed in 100 mM Tris-HCl pH 7.5, 0.1 mM EDTA, 10 mM MgCl₂, 10 mM NH₄Cl. Initially, the ligand chamber contains 100 μM SAM (containing 0.87 Ci/mmoll of [3H]-SAM, Perkin Elmer) and the protein chamber 120 μM of Trm9-Trm112 complex. After 3 h rotation at 4°C, the SAM content of chambers is determined using a Beckman Coulter LS6500 scintillation counter.
The tRNAs obtained after cleosides 2D thin layer chromatography for detection of modified nucleosides carried radiolabeled methyl group was revealed by UV shadowing. The position of the four major mononucleosides (pA, pG, pU, and pC) were revealed by phosphorimaging and compared with that of the control. First dimension chromatography was performed in solvent A, and the second in either solvent B or C. The charmm27 force field was used (40). The complex was subsequently minimized in the charmm software (41) using the powell algorithm and 10 000 steps of minimization.

**2D thin layer chromatography for detection of modified nucleosides**

The tRNAs obtained after in vitro methylation using [14C]-SAM (containing 6.5 μL of [14C]-SAM (58 mCi/mmole, Perkin Elmer)) were extracted with phenol/chloroform and ethanol precipitated. The tRNA pellet was dissolved in 10 μL of 50 mM ammonium acetate pH 5.3 supplemented with 1 μg of P1 nuclease from Penicillium citrinum (Sigma) and incubated overnight at 37°C. Digested tRNAs (2 μL) were mixed with 12μg of cold 5' P-mononucleosides pA, pU, pG and pC and spotted on a CEL-300 cellulose plate (Merck). 5' P-mononucleosides were separated using chromatographic solvents A, B or C as previously described (42). First dimension chromatography was performed in solvent A, and the second in either solvent B or C. The positions of the four major mononucleosides (pA, pG, pU and pC) were revealed by UV shadowing. The position of mcm5U nucleoside carrying radiolabeled methyl group was revealed by phosphorimaging and compared with that of reference maps obtained under identical experimental conditions (43).

**RESULTS AND DISCUSSION**

**Structure of the YTRm9-Trm112 complex**

To determine the crystal structure of the Trm9-Trm112 complex, we expressed in Escherichia coli and purified this complex from different organisms (S. cerevisiae (Sc), Schizosaccharomyces pombe (Sp), E. coli (Ec) and Yarrowia lipolytica (Yl)). Unfortunately, no crystals could be obtained from these complexes formed by full-length proteins. Analyses of these purified complexes stored at 4°C for several weeks by SDS-PAGE followed by mass spectrometry peptide mass fingerprint revealed degradation of the N-terminal extremity from YTRm9. Therefore, two truncated YTRm9 forms lacking residues 1–18 or 1–37 (hereafter named YTRm9N19 and YTRm9N38, respectively) were cloned, co-expressed with YTRm112 and purified. Compared to full-length YTRm9-Trm112 complex, both truncated forms were strongly affected in their enzymatic activity of methylation toward a tRNA mixture isolated from a S. cerevisiae trm9Δ strain but displayed the same affinity for SAM, indicating that the N-terminal residues deleted in these constructs are required for optimal enzymatic activity (Supplementary Figure S1). Diffracting crystals were obtained for the YTRm9N38-Trm112 complex and its structure was solved by the MAD method using the anomalous signal of the zinc atom bound to Trm12. The final model was refined to 2.5 Å and yielded R and Rfree values of 19.9% and 24.2%, respectively (Table 1, see Supplementary Figure 52 for electron density maps).

YTRm9N38 adopts the typical fold of the class I SAM-dependent MTases composed of a central seven-stranded β-sheet surrounded by two α-helices on each side (Figure 1A). A twisted two-stranded antiparallel β-sheet (strands βA and βB) is inserted between strand β5 and helix αE and forms a lid positioned on top of the C-terminal extremity of the β-sheet. YTRm112 is formed by a zinc binding domain made of two α-helices (α1–2) and a four-stranded antiparallel β-sheet as well as a helical domain of 3 α-helices (α3 to α5). The YTRm112 structure is very similar to the crystal structures of ScTrm112 either in its free form (13) or bound to Bud23 (15) (rmsd = 1.21–1.38 Å; 49% sequence identity). The only major difference between YTRm112 and free ScTrm112 results from a rearrangement of the C-terminal extremity from YTRm112 (corresponding to residues F122–L124). A similar rearrangement of this Trm112 region is also observed in the MtbQ-Trm112 and Bud23-Trm112 complexes and is required to avoid a steric clash between this Trm112 fragment and its MTase partner (26).

Trm9 binds mainly to Trm112 zinc-binding domain via a parallel β-zipper interaction formed by Trm9 strand β3 and Trm112 strand β4, which results in the formation of an extended eleven-stranded β-sheet (Figure 1A and B). Complex formation engages an interface area of 1160 Å² involving 20 and 21 residues from Trm112 and Trm9, respectively (Figure 1D and E). At the center of this interface, hydrophobic residues (M1, F8, V9, F43, M47, I119, P120 and F112) from Trm112 contact hydrophobic side chains from Trm9 (V59, F78, V102, A110, P112 and F116), thereby shielding this Trm9 region from exposure to solvent (Figure 1B and C). This explains the need to express Trm112 with Trm9 in E. coli to obtain soluble and active Trm9. This hydrophobic core is surrounded by several hydrogen bonds and salt bridges (see Supplementary Table S1 for details). Among these, the β-zipper interaction is realized by two hydrophobic bonds engaging main chain atoms from Trm9 V103 as well as P120 and F112 from Trm112 (Figure 1B). Other hydrogen bonds are formed by E100 from Trm9 with K2 and T5 from Trm112, by R115 from Trm9 with N7 and the carbonyl group of R50 from Trm112 and by A110 and E113 from Trm9 with Q10 from Trm112 (Figure 1B and C). Finally, a salt bridge is formed between Trm9 D117 and Trm112 R50. Among the Trm9 residues engaged in complex formation, E100, V102 and F116 from YTRm9 correspond to N89, L91 and F105 from ScTrm9, which substitutions by Lys, Arg and Glu, respectively, were previously shown to disrupt and inactivate the ScTrm9-Trm112 complex (26). It is noteworthy that the truncation of residues 263–279 from ScTrm9 resulted in loss of interaction with Trm112 (11).
Figure 1. Structure of the YfTrm9-Trm112 complex. (A) Ribbon representations of the crystal structure of the YfTrm9N38-Trm112 complex (left) and of the model of the YfTrm9N20-Trm112 complex (right). On the left panel, residues 39–44, which adopt different conformations between our crystal
The corresponding residues from YTrm9 (residues 214–234) constitute strands β6 and β7 and are not directly involved in Trm12 interaction. Hence, the loss of interaction with Trm112 most likely results from incorrect folding of this Trm1 truncated form.

Active site mapping

Despite extensive efforts, we could not obtain crystals of the YTrm9-Trm112 or YTrm9N38-Trm112 complexes bound to SAM or SAH. We have then modeled a SAM molecule by superimposing onto YTrm9 structure our SAM-bound structure of the ScBud23-Trm112 complex (15) (rmsd of 2 Å over 134 Ca atoms; 19% sequence identity). We have further observed that upon SAM binding, ScBud23 N-terminal region folds as an α-helix that lies onto SAM. In addition, a similar α-helix is present in the structure of RPA2492 from *Rhodopsseudomonas palustris*, the protein sharing the highest structural similarity with Trm9 (Supplementary Figure S3A; rmsd of 1.9 Å over 200 Ca atoms; 17% sequence identity; PDB code: 3E23). Finally, secondary structure predictions for the N-terminal region from Trm9 proteins strongly suggest that this region has indeed a high propensity to fold as an α-helix. Based on these observations, in our model of the YTrm9-Trm112 complex bound to SAM, residues 20–45 from YTrm9 fold as two α-helices (Figure 1A) and the side chains from YTrm9 Y29 and F36 (ScTrm9 Y18 and F25) match with RPA2492 Y17 and Y24, and are located onto SAM, further validating our model (Supplementary Figure S3B). Finally, in this model, the Trm9 loop connecting strands β3 and β4 is sandwiched between Trm112 on one side and SAM on the other. As shown for Mtq2-Trm12 (26), Trm12 could stabilize this loop and hence confer SAM binding activity to Trm9. This would then rationalize in part the role of Trm112 in Trm9 activation.

Mapping of the sequence conservation at the surface of this model reveals the presence of a patch formed by highly conserved residues centered on the SAM methyl group (Figure 2A). Several residues from this patch (H24, R29, K31, H115, H116, W145, Q149, W168, R241, Y243, D270 and N271; for clarity, ScTrm9 numbering will be used in this paragraph as functional analyses were performed in *S. cerevisiae*, see Table 2 for correspondence between *S. cerevisiae* and *Y. lipolytica* numbering) or from other Trm9 regions (R122 and E148) were mutated into alanine to test their role in *S. cerevisiae* Trm9 activity. As a control, we have also considered the D72A catalytic mutant deficient in SAM binding (26). Mutations were introduced into the chromosomal copy of *S. cerevisiae* *TRM9* gene and the activity of these mutants was first tested in *vivo* using the zymocin killer eclipse assay. While seven mutants (H24A, K31A, H115A, R122A, E148A, Q149A and D270A) exhibited the same phenotype as WT Trm9, eight mutants (R29A, D72A, H116A, W145A, W168A, R241A, Y243A and N271A) were resistant to zymocin suggesting that their tRNA modification enzymatic activity is strongly impaired (Table 2 and Figure 2B). These eight mutants as well as two zymocin sensitive mutants (H115A and Q149A) affecting residues directly oriented toward the putative active site were selected for further functional analyses. Co-immunoprecipitation experiments demonstrated that the loss of in *vivo* activity of these mutants is not due to disruption of the Trm9-Trm112 complex (Figure 2C). This further indicated that all these mutants accumulate in the cells although to various extents depending on the mutants and that these mutations might directly impact the enzymatic activity of the complex.

All these complexes were expressed in *E. coli* and exhibited the same purification profile as the wild-type complex strongly suggesting that they are properly folded. The *S. cerevisiae* Trm9-Trm112 complex was previously demonstrated to convert cm3U into mcm3U using SAM as methyl donor (44) and we have confirmed this by 2D-TLC (Supplementary Figure S4A). We have further measured the *in vitro* enzymatic activity of Trm112-Trm9 mutants at pH 7.5, which corresponds to the optimum of activity (Supplementary Figure S4B and C), by using [3H]-SAM and total tRNAs purified from *S. cerevisiae* trm9Δ strain as substrates. As this mixture of tRNAs contains both substrate tRNAs and non-substrate tRNAs, the latter potentially developing inhibitory effect on Trm9 activity, only apparent kinetic properties (initial velocity, specific activity, *Km* and *kcat*) could be determined. Among the mutants exhibiting zymocin resistance in *vivo*, the D72A, H116A, W145A and W168A mutants were inactive while the R29A, R241A, Y243A and N271A mutants exhibited apparent specific activities at least one order of magnitude lower than the ScTrm9-Trm112 WT enzyme (Figure 2D, Table 2). The two mutants associated to the zymocin sensitivity phenotype proved to be only slightly affected (H115A) or as active (Q149A) as the wild-type enzyme, respectively. Hence, the effect of mutations on both zymocin phenotype and enzymatic activity are correlated. Interestingly, the H115A and Y243A mutants, which modify the same amount of tRNA after 1 h in our experimental conditions, exhibit sensitive and resistant zymocin phenotype, respectively. From detailed kinetics analysis, it appears that Y243A mutant ex-
Figure 2. Trm9 active site mapping. (A) Mapping of the sequence conservation score at the surface of the YlTrm9-Trm112 model. Coloring is from gray (low conservation) to blue (highly conserved). The conservation score was calculated using the CONSURF server (50). (B) Analyses of the zymocin phenotype of yeast mutant strains by eclipse assay. Each S. cerevisiae mutated strain was subjected to killer eclipse assay with the Kluyveromyces lactis AWJ137 killer strain (top) and the Kluyveromyces lactis NK40 non-killer strain (as a control, bottom). The presence or absence of an eclipse around the killer strain shows the sensitivity or resistance of the mutated strain to zymocin toxin, respectively. Resistant and sensitive strains are labeled in red and green, respectively. (C) Effect of Trm9 mutations on ScTrm9/ScTrm112 in vivo interaction. Soluble protein extracts (Input: 1/50th of total proteins, i.e. 10 μg) and immunoprecipitates (IP: 1/100th of immunoprecipitated material) were subjected to 15% SDS–PAGE analysis and immunoblotted using mouse anti-Myc (Trm9–13Myc) or rabbit anti-Trm112 as primary antibodies and sheep anti-mouse or sheep anti-rabbit HRP-conjugated IgG as secondary antibodies, respectively. Note that for the anti-myc probing, the lower bands observed in some of the input lanes result from Trm9-myc protein degradation whereas the band observed in the IP lanes comes from mouse primary antibody heavy chain cross-reacting with anti-mouse secondary antibody. IP were performed using 9E10 anti-myc monoclonal antibodies. (D) Enzymatic activity of Trm112-Trm9 mutants. The curves obtained after fitting of the experimental data with equation given in the Materials and Methods section are shown by lines using the same color code as for the symbols. (E) Detailed representation of the YlTrm9 active site. Side chains from residues which substitution by Ala strongly (brown) or only weakly (green) affect enzymatic activity are shown as sticks. For clarity, ScTrm9 numbering is used. A manually docked cm5U nucleotide is shown as beige sticks and potential hydrogen bonds that it could form with Trm9 active site residues are depicted by dashed black lines. The modeled SAM molecule is shown as blue sticks and the methyl group to be transferred is shown as a sphere.
hibits reduced specific activity compared to the H115A mutant (Table 2). Therefore the threshold of Trm9 specific activity determining the cell phenotype toward zymocin lies somewhere in the window of specific activities defined by H115A and Y243A mutants. This indicates that the zymocin resistance phenotype in vivo is an effective tool for selecting mutants with significantly depressed Trm9 activity compared to the WT, phenotype toward zymocin switching from sensitive into resistant when in vitro Trm9 apparent specific activity is between 25% (H115A, sensitive) and 10% (Y243A, resistant) of the WT. We finally verified that the inactivation of these mutants did not result from defect in SAM binding using equilibrium dialysis (Table 2). As expected, the D72A mutant is inactive due to its complete loss of SAM binding capacity. The other mutants were still able to bind SAM although to different extent compared to WT complex. For these mutants, we do not observe any correlation between enzyme specific activity and SAM binding measurements, indicating that the decrease/loss of enzyme activity cannot be attributed to its reduced ability to bind SAM. Altogether, these results strongly suggest that the H116A, W145A, W168A, Y243A and to a lesser extent R29A, R241A, N271A and H115A ScTrm9 mutants affect enzyme activity due to the direct involvement of these residues in catalysis or in binding of tRNA substrate.

**Substrate binding and catalytic mechanism**

Our site-directed mutagenesis strategy on strictly conserved residues surrounding the SAM methyl group in the *YtTrm9N38-121* crystal structure has led to the identification of several Trm9 residues crucial for formation of *mm*U34 in some tRNAs (Figure 2B–D). The Trm9-Trm112 complex catalyzes the O-methylation of the carboxylic function of the carboxymethyl group of *mm*U34. Due to the nucleophilic property of oxygen atoms, it is generally assumed that the methyl transfer reaction occurs through a direct SN2 mechanism with the nucleophilic attack of the substrate (mmU) on the electrophilic SAM methyl group to form the methyl ester product (mm5U) and SAH (45). Such reaction requires the strict orientation of the incoming nucleophile to be optimal.

The comparison of previously described structures of MTases methylating carboxylic acids (i.e. TYW4 MTase, which is involved in the synthesis of wybutosine in Phe-tRNA (46), glutamate MTase CheR (47) and human LCMT-1 (48), which modifies the C-terminal leucine from PP2A) shows that two structurally conserved residues, an Arg and a Tyr (respectively R73 and Y203 in human LCMT-1), point toward the SAM methyl group and are ideally positioned to orient the substrate carboxylic group through electrostatic interactions (Supplementary Figure S5A). In our structure, the strictly conserved YtTrm9 H127, corresponding to ScTrm9 H116, which is crucial for enzymatic activity, structurally matches with Y203 from LCMT-1 (Supplementary Figure S5B). The H127 side chain forms a hydrogen bond with Y193 (Y242 in ScTrm9) carboxyl group from strand βB through its N9 and atom whereas the Nε2 atom forms a hydrogen bond with a water molecule. This water molecule, also coordinated by H126 (H127 in ScTrm9), point toward the SAM methyl group and are ideally positioned to participate to the correct positioning of one of the oxygen atoms from the *mm*U carboxylic group.

*Apparent specific activity (fmol of tRNA methylated/min/μmol of enzyme) calculated from apparent initial velocity. The kinetics were performed with 1.5 pmol of enzyme.

*These are relative values calculated fixing WT as 100%.

*These values were determined by fitting the data using the Michaelis- Menten equation.

ND: Not determined.

The inactivation of these mutations did not result from defect in SAM binding using equilibrium dialysis (Table 2). As expected, the D72A mutant is inactive due to its complete loss of SAM binding capacity. The other mutants were still able to bind SAM although to different extent compared to WT complex. For these mutants, we do not observe any correlation between enzyme specific activity and SAM binding measurements, indicating that the decrease/loss of enzyme activity cannot be attributed to its reduced ability to bind SAM. Altogether, these results strongly suggest that the H116A, W145A, W168A, Y243A and to a lesser extent R29A, R241A, N271A and H115A ScTrm9 mutants affect enzyme activity due to the direct involvement of these residues in catalysis or in binding of tRNA substrate.
in the catalysis and might play the same role as the R/Y dyad in TYW4, CheR and LCMT-1 active sites, i.e. positioning the substrate carboxylate group (cm^3U in the case of Trm9-Trm112) for the nucleophilic attack onto SAM methyl group.

Furthermore, most of the strongly affected Trm9 mutants studied here are oriented toward the SAM methyl group to be transferred onto the cm^3U and are very likely to directly participate in the optimal orientation of the cm^3U nucleotide from the tRNA substrates into the active site. We have then manually docked a cm^3U nucleotide into the Y/Trm9-Trm112 active site (Figure 2E). In this model, N222 side chain (N271 in ScTrm9) forms bidentate hydrogen bonds with the O2 and N3 atoms from U34 and then could be responsible for the selective recognition of pyrimidine ring at the wobble position. H126 (H115) forms a hydrogen bond with the O4 atom from U34 allowing Trm9 discriminating between U and C. In addition, a slight reorientation of W156 side chain (W145) into the Trm9 active site would allow it to stack onto the U34 pyrimidine ring. R192 (R241) and Y29 (Y18, not mutated in this study) side chains are also within hydrogen bond distances from the cm^3U carboxylic group. Finally, the W179 indole ring (W168 in ScTrm9) is solvent-exposed and could stack against the ring of a nucleotide adjacent to U34. Last but not least, in this model, the U34 3' and 5' positions are oriented outward the active site and hence, this model is consistent with the binding of a tRNA molecule.

We have next performed kinetic analyses on the WT, R29A, H115A, R241A, Y243A and N271A Trm9 mutants to investigate the role of these residues in tRNA modification (Table 2). Overall, compared to WT Trm9-Trm112 complex, all the mutant complexes are strongly affected in their apparent K_m for tRNA (from 4- to 12-fold increase) and in their k_cat (up to 100-fold decrease) whereas their K_m for SAM is much less affected (up to 4-fold). The R29A, H115A and Y243A mutants exhibit a strict correlation between the increase of K_m for tRNA and the decrease of k_cat which indicates these residues play an equally important role in the binding of the tRNA and in the catalysis whereas their respective K_m for SAM are either unchanged (R29A) or only slightly increased (H115A and Y243A). This clearly demonstrates the involvement of these residues in the binding of the tRNA substrate rather than in the binding of SAM. For the R241A and N271A mutants, the overall effect on K_m is the same as described above (K_m for tRNA significantly more affected than K_m for SAM) with a more dramatic decrease of k_cat, which may also account for the catalytic instability of these complexes during the assay. Altogether, the joint effect of mutations observed on the K_m for tRNA and k_cat support that the conserved residues are involved in tRNA binding and participate directly in the proper orientation of the cm^3U34 substrate into the active site, which is required for optimal methyl transfer reaction by the SN2 mechanism.

**Comparison with other Trm112-MTase complexes**

Trm112 interacts with and activates four MTases that adopt (Trm9, Mtq2 and Bud23) or are predicted to adopt (Trm11) the same fold. To date, we have determined the crystal structures of complexes between Trm112 and three MTase partners (Mtq2, Bud23 and Trm9, (15, 26) and this study). Interestingly, all these 3 MTases interact in a very similar manner with Trm112 as illustrated by the superimposition of the Y/Trm9-Trm112 complex onto ScBud23-Trm112 (rmsd value of 2.1 Å) and Ec/Mtq2-Trm112 complexes (rmsd value of 3 Å; Figure 3A and B). As expected from phylogenetic distance between these organisms, the Mtq2-Trm112 complex from the E. cuniculi parasite is the most divergent among the three complexes, and the two complexes formed by fungal proteins share more similarities. This comparison clearly indicates that the previously proposed competition between these MTases to interact with Trm112 is not due to slightly overlapping binding sites but to binding of these MTases to exactly the same region from Trm112. Although these structures are derived from complexes originating from different organisms, this offers the unique opportunity to compare their binding modes and to understand the molecular mechanisms allowing Trm112 to interact with four structurally similar MTases sharing less than 20% sequence identity within the same organism. We therefore generated a structure-based sequence alignment of Y/Trm9, Ec/Mtq2 and Sc/Bud23 and extended this alignment by including Sc/Mtq2, Sc/Trm9 and Sc/Trm11 sequences (Figure 3A). From this alignment, we assume that Sc/Mtq2 and Sc/Trm9 residues that align with Ec/Mtq2 and Y/Trm9 residues involved in the interaction with Ec/Trm112 and Y/Trm112, respectively, are also contacting Sc/Trm112. As previous studies have shown that over-expression of Sc/Trm9 decreases the amount of Sc/Trm11 immunoprecipitated with Sc/Trm11 (11), we also assume that Trm11 and Trm112 interact the same way, although no structure of this complex is available yet. Hence, we propose that Sc/Trm11 residues aligning with interface residues from the other MTases are engaged in the interaction with Sc/Trm112 (Figure 3A).

The structural comparison between these Trm112-MTase complexes as well as the structure-based alignment of the MTase protein sequences (Figure 3A). From this alignment, we assume that Sc/Mtq2 and Sc/Trm9 residues that align with Ec/Mtq2 and Y/Trm9 residues involved in the interaction with Ec/Trm112 and Y/Trm112, respectively, are also contacting Sc/Trm112. As previous studies have shown that over-expression of Sc/Trm9 decreases the amount of Sc/Trm11 immunoprecipitated with Sc/Trm11 (11), we also assume that Trm11 and Trm112 interact the same way, although no structure of this complex is available yet. Hence, we propose that Sc/Trm11 residues aligning with interface residues from the other MTases are engaged in the interaction with Sc/Trm112 (Figure 3A).

The structural comparison between these Trm112-MTase complexes as well as the structure-based alignment of the MTase proteins allow us to identify several common features, which could explain the ability of Trm112 to interact with its four MTase partners. First, a β-zipper interaction is formed between strand β4 from Trm112 and strand β3 from the various MTases (Figure 3B). Such interaction is formed between strand β4 from Trm112 and strand the molecular mechanisms allowing Trm112 to interact with four structurally similar MTases sharing less than 20% sequence identity within the same organism. We therefore generated a structure-based sequence alignment of Y/Trm9, Ec/Mtq2 and Sc/Bud23 and extended this alignment by including Sc/Mtq2, Sc/Trm9 and Sc/Trm11 sequences (Figure 3A). From this alignment, we assume that Sc/Mtq2 and Sc/Trm9 residues that align with Ec/Mtq2 and Y/Trm9 residues involved in the interaction with Ec/Trm112 and Y/Trm112, respectively, are also contacting Sc/Trm112. As previous studies have shown that over-expression of Sc/Trm9 decreases the amount of Sc/Trm11 immunoprecipitated with Sc/Trm11 (11), we also assume that Trm11 and Trm112 interact the same way, although no structure of this complex is available yet. Hence, we propose that Sc/Trm11 residues aligning with interface residues from the other MTases are engaged in the interaction with Sc/Trm112 (Figure 3A).

The structural comparison between these Trm112-MTase complexes as well as the structure-based alignment of the MTase protein sequences (Figure 3A). From this alignment, we assume that Sc/Mtq2 and Sc/Trm9 residues that align with Ec/Mtq2 and Y/Trm9 residues involved in the interaction with Ec/Trm112 and Y/Trm112, respectively, are also contacting Sc/Trm112. As previous studies have shown that over-expression of Sc/Trm9 decreases the amount of Sc/Trm11 immunoprecipitated with Sc/Trm11 (11), we also assume that Trm11 and Trm112 interact the same way, although no structure of this complex is available yet. Hence, we propose that Sc/Trm11 residues aligning with interface residues from the other MTases are engaged in the interaction with Sc/Trm112 (Figure 3A).

The structural comparison between these Trm112-MTase complexes as well as the structure-based alignment of the MTase proteins allow us to identify several common features, which could explain the ability of Trm112 to interact with its four MTase partners. First, a β-zipper interaction is formed between strand β4 from Trm112 and strand β3 from the various MTases (Figure 3B). Such interaction mode implies formation of a hydrogen bond network between main chain atoms from both partners and hence is less altered by side chain variations at these positions of the four MTases. Second, Trm112 shields from the solvent a hydrophobic zone on these three MTases. Although the side chains corresponding to this hydrophobic core in the four MTases from S. cerevisiae exhibit some degree of variation (Figure 3C), the hydrophobic character of this core is conserved thereby explaining Trm112 solubilizing effect on most of these MTases. Finally, three electrostatic hot spots are conserved between fungal Sc/Bud23-Trm112 and Y/Trm9-Trm112 crystal structures. The first one involves E100 from Y/Trm9 (N89 from Sc/Trm9) that forms hydrogen bonds with K2 and T5 residues from Y/Trm112 (Supplementary Table S1; Figure 3D), Y/Trm9 E100 strictly matches with D94 from Sc/Bud23, which is also engaged in hydrogen bonds with K2 and T5 residues from Sc/Trm112. In Sc/Mtq2 and Sc/Trm11, the corresponding residues are
E101 and D268, respectively. Hence, in *S. cerevisiae*, the side chains found at this position of the four MTases have a similar size and possess a carbonyl group that can be engaged in hydrogen bonds with K2 and T5 from *Sc*Trm112. This is supported by our earlier observation that the substitution of N89 by Lys in *Sc*Trm9 (in combination with L91R mutation) prevents complex formation and therefore inactivates Trm9 (26). The second hot spot that is salt bridge formed between YrTrm9 D117 with YrTrm112 R50 and between ScBud23 D112 with ScTrm112 R53 (Figure 3E). An Asp residue is conserved at this position in all MTases interacting with ScTrm112 (Figure 3A) and we propose that a salt bridge between this Asp and ScTrm112 R53 occurs in all these Trm112-MTase complexes. We previously observed that although such interaction did not exist in the structure of the EcMtg2-Trm112 complex due to discrepancy in the Trm112 central domain containing this Arg residue, the ScTrm112 R53E mutation strongly reduced the solubility and the stability of ScMtg2 and resulted in complete loss of enzyme activity (26). The third hot spot consists in three hydrogen bonds formed by YrTrm9 R115 side chain with N7 main chain and side chain carbonyl groups and R50 carbonyl group from YrTrm112 (Figure 3E). In our structural alignment, a basic residue is not conserved at the position corresponding to YrTrm9 R115 (T104 in ScTrm9, Q115 in ScMtg2, V284 in ScTrm11 or S110 in ScBud23). However, the guanidinium group from ScBud23 R107 occupies exactly the same position as the guanidinium group from YrTrm9 R115 and forms the same hydrogen bonding network with the N7 (also N7 in YrTrm112) main chain and side chain carbonyl groups and the carbonyl group from ScTrm112 R53 (R50 in YrTrm9). In our alignment, the residues corresponding to ScBud23 R107 are K101 in ScTrm9, R280 in ScTrm11 and R112 in ScMtg2, indicating that this interaction network can exist in all these ScTrm112-MTase complexes. Hence, these three crystal structures of Trm112-MTase complexes help us to understand in detail the structural plasticity that allows the small Trm112 protein to interact through the same mechanism with four MTases adopting the same fold but sharing less than 20% sequence identity.
To go deeper into the understanding of Trm112 ability to interact with various MTases, we have tested whether YITrm9, which shares 59% sequence identity with ScTrm9, could functionally complement for the deletion of TRM9 gene in S. cerevisiae and therefore could form a hybrid complex with ScTrm12. First, we have performed enzymatic assays with the purified full-length YITrm9-Trm112 complex and tRNAs purified from S. cerevisiae trm9Δ strain as substrates. We observe that the YI complex is functional on S. cerevisiae tRNAs and exhibits only a 3-fold decrease in apparent specific activity compared to Sc complex in vitro (Table 2).

Furthermore, according to its apparent specific activity, the YI complex should be associated with zymocin sensitivity phenotype in vivo (Table 2). Next, we have used an in vivo complementation approach in S. cerevisiae to characterize the biological activity of full length YITrm9. Following the replacement of genomic ScTRM9 gene by YITRMYl gene (under the control of the ScTRM9 natural promoter), the plasmid-driven expression of YITrm9 renders the strain sensitive to zymocin, indicating that an active YITrm9-YITrm112 complex can assemble and methylates Sc tRNAs in vivo (Figure 3F). In the absence of ectopic YITrm112 (i.e. in the presence of the sole endogenous ScTrm112), the strain is more resistant to zymocin indicating a defect in YITrm9 activity. As YITrm9 is proved to be efficiently expressed and active in S. cerevisiae, the latter phenotype observed could account for the lack of interaction between YITrm9 and ScTrm112. To test whether the likely competition between YITrm9 and Sc natural partners (Bud23, Mtq2 and Trm11) for ScTrm112 could be responsible for this phenotype, we considered the potential effect of increasing ScTrm112 expression level on cell phenotype toward zymocin. Plasmid-driven expression of ScTrm112 resulted in zymocin sensitivity level comparable to the one previously obtained with YITrm112 (Figure 3F). This indicates that ScTrm112 (50% sequence identity with YITrm112) is able to activate YITrm9 in vivo to a similar extent as YITrm112. This most likely occurs through a direct interaction between ScTrm112 and YITrm9 (59% and 79% sequence identity and similarity with ScTrm9, respectively). It should be noted that this chimeric YIITrm9-ScTrm112 complex is probably less stable than the corresponding complex formed by proteins from the same organism as it is necessary to increase expression level of ScTrm112 to enhance zymocin sensitivity. This is further supported by preliminary co-IP experiments showing that no YITrm9-ScTrm112 interaction could be characterized using a routine protocol suitable for measuring ScTrm9-ScTrm112 interaction.

Altogether, these results show that MTase-Trm112 binding mode is compatible with the formation of chimeric complexes between proteins from different organisms as illustrated by the ability of ScTrm112 to activate YITrm9, which shares about 60% sequence identity with ScTrm9. This is further supported by the ability of ABH8 (and hTrm9L) and WBSCR22 (Bud23 orthologue) human genes to partially complement the deletion of TRM9 and BUD23 genes in S. cerevisiae, respectively (24).

CONCLUSION

The structure of the Trm9-Trm112 tRNA MTase holoenzyme combined with functional studies has allowed the mapping of its active site and enabled us to propose a model of the catalytic mechanism and binding mode of the cm2U moiety of the tRNA substrate. In addition, the detailed comparison of this structure to those of ScBud23-Trm112 and EcMtq2-Trm112 complexes highlights that during evolution, sequences of all these proteins within the same organism have evolved in a concerted manner so as to maintain the Trm112 ability to interact with its MTase partners that share less than 20% sequence identity.

ACCESSION NUMBERS

The atomic coordinates and structure factors have been deposited into the Brookhaven Protein Data Bank under accession numbers (5CM2).

SUPPLEMENTARY DATA

Supplementary Data are available at NAR Online.

ACKNOWLEDGEMENTS

We are indebted to M. Argentini and D. Cornu for mass spectrometry analysis (SICaps, IMAGIF Platform, GIF/Yvette, France), to Dr V. Heurgué-Hamard for her help with MTase assay and for sharing with us plasmids and antibodies directed against S. cerevisiae Trm9-Trm112 complex. We thank Dr G. Bourgeois for helpful discussion and advices. We thank Dr B. Séraphin, Dr K. Breunig and Dr R. Schaffrath for sharing reagents with us. We acknowledge SOLEIL for provision of synchrotron radiation facilities.

FUNDING

This work was supported by the Centre National pour la Recherche Scientifique (CNRS) including a specific support by the ATIP-AVENIR program [to M.G.], the European Union Sixth Framework program ‘3D-Repertoire’ [LSHG-CT-2005-512028], the Agence Nationale pour la Recherche (ANR; ANR14-CE09-0016-02), the University Paris-Sud and Ecole Polytechnique. J.L. and T.V.N. hold a PhD fellowship from the French Ministère de l’Enseignement Supérieur et de la Recherche (MESR).
