Background. Low lean mass is potentially clinically important in older persons, but criteria have not been empirically validated. As part of the FNIH (Foundation for the National Institutes of Health) Sarcopenia Project, this analysis sought to identify cutpoints in lean mass by dual-energy x-ray absorptiometry that discriminate the presence or absence of weakness (defined in a previous report in the series as grip strength <26 kg in men and <16 kg in women).

Methods. In pooled cross-sectional data stratified by sex (7,582 men and 3,688 women), classification and regression tree (CART) analysis was used to derive cutpoints for appendicular lean body mass (ALM) that best discriminated the presence or absence of weakness. Mixed-effects logistic regression was used to quantify the strength of the association between lean mass category and weakness.

Results. In primary analyses, CART models identified cutpoints for low lean mass (ALM <19.75 kg in men and <15.02 kg in women). Sensitivity analyses using ALM divided by body mass index (BMI: ALM/BMI) identified a secondary definition (ALM/BMI <0.789 in men and ALM/BMI <0.512 in women). As expected, after accounting for study and age, low lean mass (compared with higher lean mass) was associated with weakness by both the primary (men, odds ratio [OR]: 6.9 [95% CI: 5.4, 8.9]; women, OR: 3.6 [95% CI: 2.9, 4.3]) and secondary definitions (men, OR: 4.3 [95% CI: 3.4, 5.5]; women, OR: 2.2 [95% CI: 1.8, 2.8]).

Conclusions. ALM cutpoints derived from a large, diverse sample of older adults identified lean mass thresholds below which older adults had a higher likelihood of weakness.

Key Words: Muscle—Sarcopenia—Cutpoints.

Received June 19, 2013; Accepted January 21, 2014

Decision Editor: Roger Fielding, PhD

Early efforts to create an operational definition of sarcopenia (including the creation of cutpoints) have relied on distributional definitions of lean mass (1), with sarcopenia defined as a value of appendicular lean mass (ALM/height2) (derived from whole-body dual-energy x-ray absorptiometry [DXA]) below the young adult mean level of lean mass or was based on definitions that further account for body size or fatness (2–4). More recent efforts have added functional and/or strength measures to lean mass to define sarcopenia (5,6), but no approaches thus far have proposed and validated cutpoints and definitions based on discriminative and predictive ability using a data-driven approach from a variety of cohort studies.
The overarching goal of this set of concurrent reports from the Foundation for the National Institutes of Health (FNIH) Sarcopenia Project was to determine preliminary data-driven criteria for clinically relevant weakness and low lean mass. The conceptual framework was based on a clinician making a “differential diagnosis” of mobility impairment, defined as slow gait speed. The clinician understands that there are many causes of slow walking, one of which is weakness. Similarly, low lean mass may be considered a potential contributing factor to the development of weakness (7). Data from multiple large cohort studies of aging were pooled for this effort (7). The first stage of analyses identified sex-specific cutpoints for weakness that discriminated slow participants (walking speed <0.8 m/s) from those who walked faster (8). In the second stage of the analyses, reported herein, we aimed to identify cutpoints in lean mass that discriminated those who were weak (grip strength <16 kg in women or <26 kg in men) from those who were stronger. The findings from this work were used to address subsequent goals of the Project, so it is important to consider these results within the context of all other articles in this series.

METHODS

Participants

The cohort studies and the clinic visit used in this phase of the FNIH Sarcopenia Project analysis included: the Study of Osteoporotic Fractures (SOF), both the original cohort (study Visit 6) (9) and African American cohort (study Visit 1) (10); the African American Fractures in Men Study (MrOS, baseline visit) (11); the Health, Aging and Body Composition Study (Health ABC, Year 6 Clinic Visit) (12); the Framingham Study Offspring Cohort (exam cycles 6 and 7, 1996–2001) (13) and Framingham Original cohort (exam cycle 22, 1992–1993) (14); the Boston Puerto Rican Health Study (BPRHS, baseline visit) (15); Rancho Bernardo (study Visit 7) (16); and several smaller clinical trials led by Dr. Anne Kenny at University of Connecticut (randomization visit for all studies) (17–22). To be included in these analyses, participants must have completed, at the time point identified above, the following measures: objectively measured height and weight; body mass index (BMI); ALM (sum of lean mass in the arms and legs), leg lean mass (LLM), and total body fat (TBF) were assessed using DXA, on Hologic 4500 machines in MrOS, Rancho Bernardo, and Health ABC; on Hologic 2000 machines in SOF (both the original and African American cohorts); and Lunar Prodigy machines in Framingham (both the Original and Offspring cohorts), BPRHS, and the clinical trials at the University of Connecticut.

Assessment of Lean Mass

ALM, LLM, and total body fat (TBF) were assessed using DXA, on Hologic 4500 machines in MrOS, Rancho Bernardo, and Health ABC; on Hologic 2000 machines in SOF (both the original and African American cohorts); and Lunar Prodigy machines in Framingham (both the Original and Offspring cohorts), BPRHS, and the clinical trials at the University of Connecticut.

Assessment of Grip Strength and the Definition of Weakness

Maximum grip strength of either hand was measured by handheld dynamometers. In the first phase of analyses (reported in an accompanying article) (8), the cutpoint for grip strength as a discriminator of slowness (defined as a walking speed of ≤0.8 m/s) was identified using classification and regression tree (CART) analysis (23). Men with a grip strength less than 26 kg and women with a grip strength less than 16 kg were defined as “weak.” A secondary cutpoint for weakness based on grip strength standardized to body size (ie, the ratio of grip strength to BMI, weakness \( \frac{\text{grip strength}}{\text{BMI}} \)) was identified for men (men with a ratio <1.0 defined as weak) and women (women with a ratio of <0.56 defined as weak.) Those analyses to identify a cutpoint in grip strength included 20,847 participants, of whom 10,036 were also included in our analyses; 1,207 participants were included in our analyses but not included in the grip strength analyses. Most of the exclusions from the grip strength analyses were due to missing data for walking speed; and most of the exclusions from the present analyses were due to missing values for body composition (ALM or body fat).

Statistical Analysis

LOESS plots were used to describe the overall shape of the relationship between lean mass (both ALM and ALM_{BMI}) with grip strength and walking speed; Pearson correlation coefficients were calculated.

CART analysis was then performed to derive clinically meaningful cutpoints for lean mass as a discriminator of weakness. CART is particularly advantageous to this study because (i) the relationship between candidate predictors and weakness does not require specification, (ii) CART can identify complex multiway interactions between potentially important variables (eg, BMI, height), and (iii) predictors and cutpoints are selected to optimize discrimination of the outcome (weakness).

CART analysis was performed using the rpart procedure of R software (version 2.10.1), and cross-validation
was used to “prune” less important splits to prevent overfitting and produce a more parsimonious tree. Cross-validation was performed by randomly partitioning the pooled data into 10 equally sized mutually exclusive data sets (ie, each set excluded 10% of the original pooled data). The tree was then applied to 10 subsamples that contained 90% of the data (ie, 10% of the data was left out of each subsample), and the prediction error from each subsample was calculated. The 10 prediction errors (error sum of squares) were used to calculate the empirical standard error of the prediction error. Following published guidelines (24), the tree was pruned to the most parsimonious tree that was within 1 SE of the tree with the smallest prediction error. This pruned tree contains the final set of lean mass cutpoints.

Several CART models were run. First, ALM and LLM were entered into a CART model as the only potential discriminators of weakness (defined as grip strength <26 kg for men and <16 kg for women). Then, body size variables (height, weight, BMI, TBF) were added to the model. Third, measures of lean mass standardized to body size (the ratio of ALM to each measure of body size) were added and included ALM<sub>height</sub>, ALM<sub>weight</sub>, ALM<sub>BMI</sub>, ALM<sub>TBF</sub>, LLM<sub>height</sub>, LLM<sub>weight</sub>, LLM<sub>BMI</sub>, and LLM<sub>TBF</sub>. Finally, we consider only ALM<sub>BMI</sub> and ALM as potential discriminators of weakness.

We report the prevalence for low lean mass by various subgroups in the cohorts (such as age, BMI, and history of disease) and the likelihood of prevalent weakness by low lean mass across these subgroups. We also report the likelihood of slowness and inability to rise from a chair by various weakness and low lean mass categories. These estimates were derived using mixed-effects logistic regression that included a random effect for cohort to account for the heterogeneity between studies.

RESULTS

ALM was positively correlated with grip strength in men ($r = .47, p < .001$) and somewhat less strongly in women ($r = .33, p < .001$) (Figure 1). ALM was only modestly positively correlated with walking speed in men ($r = .11, p < .001$) and was inversely correlated with walking speed in women ($r = -.20, p < .001$). ALM<sub>BMI</sub> was positively correlated with grip strength ($r = .42, p < .001$) and walking speed ($r = .24, p < .001$) in men as well as in women (grip strength, $r = .22, p < .001$ and walking speed, $r = .07, p < .001$). Body weight was strongly correlated with ALM in both men ($r = .80, p < .001$) and women ($r = .81, p < .001$).

The CART models for the primary definition of weakness (grip strength <16 kg in women and <26 kg in men) demonstrated that ALM was the best discriminator of weakness, regardless of inclusion of body size variables (weight, TBF, height, height<sup>2</sup> or BMI) or lean mass variables standardized to body size, or both. (Figure 2).

In men, a single cutpoint for ALM was found. Men with an ALM less than 19.75 kg were defined as having low lean mass; the prevalence of weakness was 18.3% in this group compared with only 2.5% for men with higher lean mass (ALM ≥ 19.75 kg).

In women, two cutpoints for ALM were found: one at 15.02 kg and another at 12.09 kg. For parsimony, and to propose a definition analogous to that for men, we defined two groups of women: those with low lean mass (ALM < 15.02 kg) and higher lean mass (ALM ≥ 15.02 kg). The prevalence of weakness for women with low lean mass was 29.8% compared with a prevalence of weakness of 11.0% for women with higher lean mass.

In secondary analyses, for men, when ALM<sub>BMI</sub> and BMI were the only potential discriminators of weakness, one cutpoint in ALM<sub>BMI</sub> was found. In these secondary analyses, we defined men with low lean mass as having a value of ALM<sub>BMI</sub> less than 0.789 (prevalence of weakness was

Figure 1. Scatterplots and correlation of appendicular lean mass (ALM) or ALM/body mass index (BMI) versus grip strength or walking speed for men and women in the FNIH (Foundation for the National Institutes of Health) Sarcopenia Project.
11.8%); men with an ALM more than or equal to 0.789 had higher lean mass and a prevalence of weakness of 2.4% (Figure 3).

In secondary analyses, for women, when ALM and BMI were the only potential discriminators of weakness included in the CART model, one cutpoint in ALM was found: 0.512 (Figure 3), and for those with ALM more than or equal to 0.512, a second cutpoint was found for BMI (23.7 kg/m²). In the secondary analyses, we defined women with low lean mass as having ALM less than 0.512 (prevalence of weakness was 31.0%); women with ALM more than or equal to 0.512 had a prevalence of weakness 16.8% (Figure 3). Of the women with ALM more than or equal to 0.512, those who had a BMI less than 23.7 kg/m² had a prevalence of weakness of 12.0%, whereas those with a BMI of more than or equal to 23.7 kg/m² had a prevalence of weakness of 24.2%.

Men with low lean mass were more likely to be weak compared with those with higher lean mass, after accounting for age and study by both the primary definition (odds ratio [OR]: 6.9 [95% CI: 5.4, 8.9]) or secondary definition (OR: 4.3 [95% CI: 3.4, 5.5]) (Table 1). Similarly, women with low lean mass were also more likely to be weak compared with those with higher lean mass by the primary definition (OR: 3.6 [95% CI: 2.9, 4.3]) or secondary definition (OR: 2.2 [1.8, 2.8]), although the strength of the association was smaller in magnitude than it was for men. For most stratified analyses, the association between low lean mass and weakness was significant ($p < .05$), while the point estimates varied by strata (although the interaction by stratifying factors was not significant for any model).

In men, when weakness and low lean mass were considered jointly in the same model with slowness as the outcome, both factors were independently associated with prevalence of slowness (Table 2). Men who were weak (either by grip strength alone or by grip strength standardized to BMI) were about 3- to 4.5-fold more likely to be slow and 2.5- to 3.0-fold more likely to be unable to rise from a chair than men who were not weak. Men with low lean mass (either by ALM or ALM/BMI) were about twice as likely to be slow compared with men with higher lean mass. Men with low lean mass by ALM, but not ALMBMI, were about 1.3- to 1.6-fold more likely to be unable to rise from a chair than men with higher lean mass.

In women, when weakness and low lean mass were considered jointly in the same model with slowness as the outcome, only weakness was consistently associated with slowness. Women who were weak (either by grip strength alone or by grip strength standardized to BMI) were 2- to 3-fold more likely to be slow than women who were not weak. One the other hand, and in contrast to results for men, women with low lean mass based on ALM had a somewhat lower likelihood of being slow or unable to rise from a chair compared with women with higher lean mass. Women with low lean mass (based on ALM/BMI) had about a 50% increased likelihood of slowness after adjustment for

---

**Figure 2.** Classification and regression tree models for measures of lean mass, body size, and lean mass standardized to body size discriminating weakness in older men and women in the FNIH (Foundation for the National Institutes of Health) Sarcopenia Project. Model included the following potential discriminators of weakness (grip strength <16 kg in women and <26 kg in men): ALM (appendicular lean mass), height, weight, height², total body fat (TBF), BMI (body mass index), ALM/height, ALM/weight, ALM/height², ALM/BMI, ALM/TBF, LLM/height (LLM = leg lean mass), LLM/weight, LLM/height², LLM/BMI, ALM/LLM, and ALM/LBM.
weakness based on grip strength alone. However, when the association between ALM and slowness was adjusted for weakness standardized to BMI, the association was not significant. ALM was not significantly associated with inability to rise from a chair for women.

When we compare the prevalence of low lean mass by our definition based on ALM with the prevalence of low lean mass by Baumgartner, overall percent agreement was 83.0% for men and 75.4% in women (Table 3). When we compare the prevalence of low lean mass by our definition based on ALM with the prevalence of low lean mass by Baumgartner, the overall percent agreement is 69.1% in men and 70.7% in women.

**DISCUSSION**

The goal of these analyses, using pooled data from several large cohort studies of older men and women, was to identify cutoffs in values of low lean mass that discriminated those who were weak from those who were not weak. Primary analyses resulted in a definition of low lean mass as ALM less than 19.75 kg in men and less than 15.02 kg in women. Sensitivity analyses suggested an alternative definition using a value of ALM standardized to BMI (ALM/BMI). Men with a value of ALM/BMI less than 0.789 and women with a value of ALM/BMI less than 0.512 were considered to have low lean mass by this secondary definition.

While our analyses were not designed to define or evaluate “sarcopenic obesity,” our results suggest that body size and potentially fatness influence the association between lean mass and weakness. This finding is similar to another report (4) that found that low lean mass based on the Baumgartner (1) criteria using ALM/height was less strongly related to physical disability than a measure of low lean mass that was adjusted for height and body fat mass (2). On the other hand, measures of obesity were not selected by the CART models as primary discriminators of weakness in older people.

The associations between our definitions of low lean mass and concurrent weakness are quite strong as would be expected by our analytical methodology. Men who had low lean mass by the primary definition based on ALM alone were about 7 times more likely to be weak (grip strength <26 kg) than men with higher lean mass. In women, the association between low lean mass and weakness was somewhat lower but still substantial, as women with low lean mass by the primary definition based on ALM alone were about 4 times more likely to be weak (grip strength <16 kg) than women with higher lean mass. However, the analysis technique employed requires caution when interpreting these data. The strong associations between our proposed definitions of low lean mass and weakness are not surprising, because of the analysis method (CART) derived the cutoffs to maximize the association between lean mass and weakness. We expressed the association between our lean mass cutoffs and weakness as ORs to further ease the clinical interpretation of our results. To understand the clinical implications of the proposed definitions of low lean mass described here, further analyses must be completed, including those of longitudinal data that would establish the predictive validity of our cutoffs and the independent association of these cutoffs with clinical outcomes thought to be related to weakness and low lean mass.

The association between low lean mass and slowness was independent of weakness in men. Men who had low lean mass (by either definition) were about 2–4.5 times more likely to be slow when compared with men with higher lean mass after accounting for weakness. On the other hand, in women, the association between low lean mass and slowness was independent of weakness in men.

*Low lean mass based on ALM criterion: <19.75 kg in men, <15.02 kg in women. Low lean mass based on ALM

There are some limitations of these analyses. First, CART, by definition, partitions data into groups, even when the underlying relationship between the predictor and outcome is linear. Second, our CART models did not account for differences between studies included in the model, although we did account for study in subsequent logistic models. Third, while we accounted for cohort study a random effect in the logistic models, we did not specifically correct or adjust values to account for differences across cohorts. For example, the cohorts used various makes and models of DXA machines. There are no methods aside from in vivo cross-calibration studies that

slowness was inconsistent across definitions and was not consistently independent of concurrent weakness. These sex differences could be due to a number of factors. Men and women have drastically different body types and body composition, and women have more disability than men. It is possible that the association between body size, lean mass, weakness, and slowness truly differs between men and women. Another possibility is that differences between single-sex cohorts in the pooled data set (such as SOF and MrOS, for example) explain the discrepant results.

Our results are not directly comparable to other proposed definitions of low lean mass or sarcopenia, because these other definitions have accounted for body size in a different manner than our analyses. For example, the Baumgartner definition (1) (which has been included in consensus statements about sarcopenia) divides ALM by height2 to quantify lean mass and then defines individuals as “sarcopenic” if their value is at least 2 SDs below a young normal mean value. This equates to 7.26 kg/m2 for men and 5.45 kg/m2 for women. We found modest agreement between our

definitions and the Baumgartner definition of low lean mass; thus, we conclude that our cutpoints and other sarcopenia definitions, as discussed in an accompanying report from this project (25), differentially classify individuals. We could not compare our definition against others that used non-DXA methods to determine lean mass (such as bioelectrical impedance analysis [BIA]) (3), because BIA was not available in most participating cohorts.

There are some limitations of these analyses. First, CART, by definition, partitions data into groups, even when the underlying relationship between the predictor and outcome is linear. Second, our CART models did not account for differences between studies included in the model, although we did account for study in subsequent logistic models. Third, while we accounted for cohort study a random effect in the logistic models, we did not specifically correct or adjust values to account for differences across cohorts. For example, the cohorts used various makes and models of DXA machines. There are no methods aside from in vivo cross-calibration studies that
can accurately compare soft tissue estimates across DXA machines (26). As the machines included in this project were located throughout the world, such a study was not feasible. Additionally, unlike T-scores for bone mineral density (BMD) in the diagnosis of osteoporosis (which are used in part to account for machine differences in BMD estimates), there are no population-based values for all the DXA manufacturers for all the soft tissue compartments that would allow calculation for T or Z scores. Finally, no statistical model alone can identify a disease state. Thus, further work is necessary to understand the biological implications of these results.

We intend for the cutpoints in ALM and ALM\(_{BMI}\) to be used within the context of the larger analysis project we describe in which we are trying to identify those older persons who are slow and weak whose impairments are likely attributable to lower levels of lean mass. We have shown that there is a level of ALM and ALM\(_{BMI}\) below which strength is lower. In another report in this series, the independent predictive validity of these lean mass cutpoints for future mobility impairment is evaluated. Given the discordant literature that suggests that lean mass may not be independently predictive of functional decline once strength is known (27), these next analyses will be imperative.

The conceptual framework we used for this larger project—that there is a clinical syndrome that includes walking speed, strength, and lean mass that identifies individuals at risk for disability—is similar to the framework described by other consensus groups that have addressed this broad topic of “sarcopenia.” However, there is not clear consensus regarding which part or parts of this clinical syndrome constitute “sarcopenia” and which should be designated by some other distinction such as “mobility impairment with clinically relevant weakness and low lean mass.” To avoid confusion, we prefer terminology that precisely describes the results. For example, we have identified values of low lean mass that discriminate weakness in older adults.

In summary, we have identified cutpoints in lean mass that discriminate those who are weak from those who are stronger; secondary analyses suggest that adjustment for body size may influence the cutpoints selected. Different values were found in men and women, given the sex differences in body size. Future analyses must evaluate the independent predictive validity of these cutpoints.

**Funding**

Support for the conference and the consortium was provided by the National Institute on Aging (U13AG041583 and P30 AG024827), the Food and Drug Administration, and through a grant from the Foundation of the NIH, supported by funds from Abbott Nutrition, Amgen, Eli Lilly, Merck, Novartis, and The Dairy Research Institute.
