Background. Little is known about the health and functioning of individuals who become centenarians in the years prior to reaching age 100. We examined long-term trajectories of disease, disability, and cognitive function in a sample of U.S. centenarians to determine how their aging experience differs from their nonsurviving cohort counterparts, and if there is heterogeneity in the aging experience of centenarians.

Methods. Data are from the 1993–2010 waves of the nationally representative Health and Retirement Study. Among those who had the potential to become centenarians, we identified 1,045 respondents who died before reaching age 100 and 96 who survived to their 100th birthday. Respondents, or their proxies, reported on diagnosis of six major diseases (hypertension, heart disease, lung disease, stroke, cancer, and diabetes), limitations in activities of daily living, and cognitive function.

Results. As they age to 100, centenarians are generally healthier than nonsurviving members of their cohort, and a number of individuals who become centenarians reach 100 with no self-reported diseases or functional impairments. About 23% of centenarians reached age 100 with no major chronic disease and approximately the same number had no disability (18%). Over half (55%) reached 100 without cognitive impairment. Disease and functioning trajectories of centenarians differ by sex, education, and marital status.

Conclusions. While some centenarians have poor health and functioning upon reaching age 100, others are able to achieve exceptional longevity in relatively good health and without loss of functioning. This study underscores the importance of examining variation in the growing centenarian population.

Key Words: Centenarians—Longevity—Disease—Functioning.

Received October 29, 2013; Accepted June 28, 2014

Decision Editor: Stephen Kritchevsky, PhD

Although centenarians are still rare in the U.S. population, the number of U.S. centenarians has grown rapidly in the past 30 years (1). Current centenarians survived to age 100 years when the median age at death for their cohort was around 70 years (2), and thus represent a unique subset of the older population. The U.S. centenarian population is projected to increase sixfold by 2050 (3). The rapid emergence of this long-lived population raises the question: Are longer lives healthier lives?

Of major concern is the possibility that additional years of life are accompanied by increased rates of disease and disability, often referred to as the “expansion of morbidity” (4). Although the exceptional longevity of centenarians is impressive, centenarians may be spending much of their added years in poor health, with a high disease burden (5) and diminished physical and cognitive functioning (6–9). Another perspective on centenarians, however, is that they are exemplars of life-long healthy aging (10,11) and that most of their additional years are healthy years. This perspective, which is consistent with the “compression of morbidity” hypothesis (12), maintains that survival to 100 years is predicated on an individual’s ability to remain healthy. Perhaps a more plausible characterization of the centenarian experience is that there is variation in health and functioning. Although as a group centenarians share the unique trait of being “longevity outliers,” they likely vary in their aging experience. Emerging studies of centenarians find that although some centenarians live with disease and diminished functioning, others remain healthy and functional (8,13,14).

Understanding the aging experience of those who become centenarians requires longitudinal data on older adults in the decades before reaching 100 years. Most prior studies of centenarians, however, are based on cross-sectional surveys that only measure health and functioning at or around 100 years of age (5–9,14–16), or use retrospective information to determine health and functioning prior to reaching 100 years of age (13,17,18). We know of one study that has examined trajectories of physical and cognitive independence in a cohort of centenarians, using multiple assessments...
of centenarians during their 90s, but this study did not directly examine heterogeneity in trajectories (19). Another limitation of existing research is that few studies have compared centenarians with appropriate controls, the nonsurviving members of their birth cohort. Two studies using data on the 1905 Danish cohort compared centenarians with their shorter-lived counterparts and found that centenarians were healthier and higher functioning over time (17,19). Making intracohort comparisons precludes cohort differences as a potential explanation for centenarians’ health advantage at older ages.

We use a national, prospective study of older U.S. adults to examine disease and functioning trajectories of centenarians and their shorter-lived cohort counterparts. We find that compared with their nonsurviving counterparts, centenarians were healthier during their 80s and 90s. There is, however, considerable heterogeneity in disease and functioning trajectories among centenarians.

**METHODS**

**Study Population**

We use data from the Health and Retirement Study (HRS), a prospective panel study that started in 1993 with a nationally representative sample of the noninstitutional U.S. population aged 70 and older. Follow-up interviews were conducted every 2 years with respondents or their proxies. The current study includes data through the 2010 interview, totaling 17 years of follow-up. The response rate at baseline was 83%, with follow-up response rates ranging from 93% to 96%. The baseline sample has been shown to correspond to the 1993 Current Population Survey for those aged 80 and older and to represent both healthy and frail older adults (20). The initial sample in 1993 only represented community-dwelling older adults, but because respondents could be interviewed in later waves in institutionalized settings, such as nursing homes, the sample also becomes representative of the institutionalized population within two survey waves (21).

Figure 1 shows how the analytic sample was selected. Respondents were included in the sample if they had the potential to survive to 100 years by 2010 and had at least one follow-up interview. Among those who were born in 1910 or earlier, we differentiate between nonsurvivors (n = 1,045)—respondents who died before reaching 100 years of age—and centenarian survivors (n = 113)—respondents who reached 100 years of age during the study period. In brief, we refer to centenarian survivors as centenarians. We also excluded centenarians who were in the study for fewer than 3 years prior to reaching 100 years or were not observed within 3 years of reaching 100 years, yielding a final sample of 96 centenarians.

Age validation is important in studies of extreme longevity because age and birth year misreporting can artificially inflate the number of centenarians. Age misreporting is more likely to occur among the very old due to lack of birth records documenting year of birth (22). Individuals in this study were born close to or after 1900 and are, therefore, more likely to accurately report their birth year (23).

![Figure 1. Sample selection flow chart.](https://academic.oup.com/biomedgerontology/article-abstract/70/2/193/2947711)
Furthermore, birth year was reported accurately by 89% of centenarians (n = 85) and nonsurvivors (n = 932) according to comparisons with birth year information recorded in Medicare data, a reliable administrative source of birth year information (24). Only one centenarian reported a birth year inconsistent with Medicare records. Birth year information could not be verified for the remaining 10 centenarians and 113 nonsurvivors. However, it is likely that centenarians for whom birth year could not be validated reported their year of birth correctly because their individual characteristics are consistent with those who correctly report their birth year: eight were white, six had at least 12 years of education and none were born in the South, where vital statistics systems were not complete until the 1930s.

Disease and Functioning Measures

We examine three dimensions of health: selected self-reported chronic diseases and conditions, disability, and cognitive function. Disease is measured with a count of the number of six selected disease and chronic conditions: hypertension; diabetes; cancer; chronic lung disease (eg, chronic bronchitis, emphysema); heart disease (eg, coronary heart disease, angina, congestive heart failure), and stroke. These represent six of the leading causes of death among adults aged 85 and older (25). Respondents who report having a doctor diagnosed disease or condition are given a score of 1, for a total score that ranges from 0 to 6.

Disability is measured using a modified Katz activities of daily living (ADL) scale (26) that consists of the following activities: walking across a room, dressing, bathing, eating, getting in and out of bed, and using the toilet. Respondents who reported any difficulty with an activity were given a score of 1, for a total score that ranges from 0 to 6.

Cognitive function is assessed with a 35-point scale that sums scores on an immediate and delayed 10-noun free-recall test to measure memory, a serial seven subtraction test to measure working memory, a backwards counting test to measure processing speed, recall of the date and name of the president and vice-president to measure orientation, and an object naming test to measure knowledge and language. These tests were adapted from the Telephone Interview for Cognitive Status and have been validated for use in population surveys (27). Scores of 8 or less indicate severe cognitive impairment in adults aged 70 and older (21,27,28).

The cognitive function assessment is administered directly to respondents. For respondents with proxies, we considered additional information that would indicate cognitive impairment. If respondents did not have a cognitive function score in a survey wave, but their proxy reported they had been diagnosed with a memory-related disease, we categorized them as being cognitively impaired at that wave and all subsequent waves. In the 2010 interview, the questionnaire was changed and respondents or their proxies were asked if a doctor had ever told them that the respondent had Alzheimer’s, dementia, senility, or other serious memory impairment.

Survival Pathways

We use an existing classification approach to define three centenarian survival pathways: escapers, delayers, and survivors (13). Escapers had no diseases or functional loss at the time of the first interview or the last interview. For instance, centenarians who showed no signs of cognitive impairment over time were considered to have escaped cognitive impairment. Delayers also had no diseases or functional loss at baseline, but had some level of disease or functional loss by the time of their last interview. For example, those who had no ADL limitations at baseline, but who were limited in at least one activity by the time they reached 100 years, were considered to have delayed disability. Survivors had some level of disease or functional loss at both the baseline and the final interview.

Statistical Analyses

We examined differences between centenarians and nonsurvivors using t tests for continuous variables and chi-square tests for categorical variables. We used one-way analysis of variance and chi-square tests to compare characteristics between survival pathways. All statistical analyses were performed using Stata 12.1. All analyses are weighted to account for differential sampling probabilities and nonresponse.

Results

Baseline characteristics of nonsurvivors and centenarians are shown in Table 1. Centenarians were older at baseline, and more likely to be female, widowed, and living alone. They also had a lower disease burden at baseline, compared with nonsurvivors. Centenarians had lower levels of disability and higher levels of cognitive function compared with nonsurvivors, but the differences were not statistically significant.

Figure 2 shows trajectories of disease, ADL limitations, and cognitive functioning by 2-year age intervals for centenarians and nonsurvivors. To account for the large cohort differences shown in Table 1, we compared trajectories of centenarians with their age-matched nonsurivor counterparts. Those who become centenarians had fewer diseases at every age (Panel A). However, the average number of diseases increased more rapidly among centenarians, resulting in a narrowing of the gap between nonsurvivors and centenarians. Similarly, centenarians had fewer ADL limitations relative to nonsurvivors (Panel B). Trajectories of cognitive functioning are shown in Panel C. There was very little difference in cognitive function between centenarians and nonsurvivors. After 96 years of age, the average cognitive
function score among centenarians declined from about 15
to just below 10 by age 100–101 years. Mean cognitive func-
tioning was calculated for a smaller number of respondents
because scores were not available from respondents who
had a proxy complete the interview.

Although centenarians are generally healthier than their
nonsurviving counterparts, there may be heterogeneity in the
centenarian aging experience. Figure 3 shows the distribution
of centenarians across the three survival pathways (escapers,
delayers, and survivors) for each of the three health indica-
tors. Over half survived to 100 years of age with at least one
disease, over half of the centenarians remained cognitively
intact (ie, escaped cognitive impairment). About 31% were
cognitively intact in their 80s and 90s, but had developed
cognitive impairment prior to reaching 100 years of age.
Only 12% of those who survived to 100 years of age were
cognitively impaired at younger ages.

Table 2 shows the distribution of sociodemographic char-
acteristics of centenarians by survival pathway for each of
the three health indicators. Those who escaped with no dis-
eases were older, on average, than those who delayed or
survived with disease. With respect to the ADL pathways,
relatively fewer women and unmarried (ie, widowed) adults
were present among ADL escapers and delayers, compared
with ADL survivors. Centenarians who escaped or delayed
cognitive impairment were younger at baseline than those
who survived with impairment, and both escapers and delay-
ers had higher education levels compared with survivors.

Disease and functioning trajectories by survivor path-
ways are shown in Figure 4. In the disease pathway (Panel
A) escapers are represented by a flat line at zero because
they survived to 100 years of age with none of the diag-
osed diseases. Delayers and survivors both experienced
increases in the number of diseases over time. Although
the line is relatively flat, ADL escapers are not represented
by a completely flat trajectory because some individuals
reported ADL limitations during the study period but then
experienced recovery from disability prior to reaching 100
years of age (Panel B). The ADL survivors have an average
of nearly two limitations at baseline, increasing to over four
limitations by 100 years of age. Although delayers do not
initially have much disability, they ultimately reach an aver-
age of nearly four limitations by 100 years of age. Escapers
and delayers have relatively high cognitive functioning
scores over time, though scores decline steeply with age for
delayers (Panel C). Survivors have consistently low scores
over time.

**Discussion**

This study confirms in a prospective, national sample of
older U.S. adults that there is significant heterogeneity
in the aging experience of centenarians prior to reaching
100 years. In general, centenarians are healthier throughout
their 80s and 90s compared with their shorter-lived cohort
counterparts. However, while some centenarians exhibited
healthy aging by either escaping or delaying disease and
functional impairment, over half of centenarians aged with
disease and about one-fifth and one-tenth aged with disabil-
ity and cognitive impairment, respectively, exhibiting aging
trajectories similar to nonsurvivors. Although these cente-
narians are living longer than most of their cohort, they are
doing so with poor health and functioning.

It has been suggested that exceptional longevity is
achieved by postponing the onset of disease and disabil-
ity (19). The majority of centenarians postponed physical
and cognitive impairment into their 90s and 100s, although
less than half made it through their 90s disease-free. Heterogeneity in the survival experience of centenarians suggests that both compression and expansion of morbidity and disability are occurring within the population of centenarians and that there are multiple paths to becoming a centenarian (29).

Our finding that 23% of centenarians escaped major diagnosed diseases is lower than the one-third of escapers
reported by Evert and colleagues (13); though the higher disease prevalence among HRS centenarians is more consistent with what has been reported in other centenarian studies that have found rates as high as 66%–72% for cardiovascular disease (5,15). We also found that only 18% of HRS centenarians had escaped disability. The prevalence of independence is much lower in our study compared with the 22%–41% reported in other studies of centenarians (5,8,18,19). Previous research on levels of cognitive functioning among centenarians is less consistent, with reports of the prevalence of cognitive impairment ranging from 37% to 100% (7–9), depending on the population and method of cognitive assessment (30). In our sample of U.S. centenarians, 55% remained cognitively intact over the study period, confirming that dementia is not an inevitable condition of living longer lives (7).

Centenarian aging trajectories differed according to sociodemographic characteristics. Consistent with what has been reported previously, women’s aging trajectories are characterized by more disability and disease than their male counterparts (6,13,14). One explanation for the gender difference is that women have a higher proinflammatory status, relative to older men, and thus a greater risk for accumulating age-related disease and disability (14). We also found that non-Hispanic whites and those with higher levels of education were more likely to remain cognitively intact, confirming that social patterning in cognitive functioning observed at earlier ages persist even among centenarians (31,32).

An increasing number of HRS respondents are surviving to 100 years of age. The HRS has, therefore, become an emergent centenarian study providing an ideal opportunity to study U.S. adults as they reach very old age and gain insights into the health and functioning trajectories of exceptionally long-lived individuals. With its prospective design, a key advantage of the HRS is the ability to compare the aging experience of centenarians with their cohort counterparts who did not survive to 100 years.

Notes: ADLs = activities of daily living. Numbers are means for continuous variables and percentages for categorical variables. Statistically significant differences (**p < .05, *p < .10) among groups from two-tailed t tests for continuous variables and two-tailed chi-square tests for categorical variables.
There are some important limitations to the study. Our list of diseases and chronic conditions is not exhaustive and is missing important age-related conditions, such as pneumonia, kidney disease, and hip fracture. We do, however, assess the major conditions that are the leading causes of death in the United States (25). Because we did not have information on the exact timing of onset for diseases and functional impairment we were unable to assess the precise amount of

Figure 4. Trajectories of diseases (panel A), ADL limitations (panel B), and cognitive function (panel C) by age and centenarian survival pathway.
time respondents lived with poor health and functioning prior to becoming centenarians. We also lacked information on disease management and severity. Over half of the centenarians in our study were diagnosed with hypertension prior to 100 years of age, but we do not know if their blood pressure was under control. There may be important unobserved heterogeneity in disease severity among delayers and survivors.

Our measures of disease and disability are self-reported and may be subject to reporting error. However, these measures have been validated for use in population surveys and are considered to be robust indicators of health and functioning in older populations (33). Moreover, previous research on older adults has found self-reported chronic diseases and ADL limitations to correlate well with medical records and direct examination (34,35). However, because we rely on self-reported disease and disability we may overlook underlying pathology, even in those centenarians who appear healthy (36).

A common concern in studies of long-lived individuals is bias introduced through selective survival of the sample. At baseline, the HRS sample represented community-dwelling older adults who were likely healthier and more functionally intact than older adults residing in institutional settings, such as nursing homes. Because the baseline sample did not include the institutionalized older adult population, we likely underestimate the baseline health and functioning differences between centenarians and their nonsurviving counterparts. Observed differences between centenarians and nonsurvivors are less subject to this selection bias over the follow-up as individuals are followed into institutions. Finally, previous research suggests there are cohort differences in the aging experience of centenarians (37,38) that we were unable to observe with our small sample. As new centenarian cohorts emerge in the HRS, future studies should investigate the differences in survival pathways between older and younger cohorts.
