**Purpose.** To determine the eye size and shape obtained by magnetic resonance imaging (MRI), and to determine associations with antenatal factors in newborn children.

**Methods.** A subset of 173 full-term newborn children from the Growing Up in Singapore Towards Healthy Outcomes (GUSTO) birth cohort underwent MRI. Eye volume and surface area were measured. Eye shape was assessed qualitatively from three-dimensional models, and quantitatively by measurement of longitudinal axial length (AL, the length from the posterior corneal surface to the retinal surface), and horizontal width and vertical height of the internal eye along the cardinal axes. Oblateness was calculated as \(1 - \frac{\text{AL}}{\text{width}}\) or \(1 - \frac{\text{AL}}{\text{height}}\). Oblate eyes had oblateness \(>+0.01\), spherical eyes had oblateness between \(+0.01\) and \(-0.01\), and prolate eyes had oblateness \(<-0.01\).

**Results.** A total of 346 eyes of 173 children were included. Mean oblateness using width was \(-0.06 \pm 0.05\) (range, \(-0.23\) to \(+0.08\)), and mean oblateness using height was \(-0.01 \pm 0.04\) (range, \(-0.19\) to \(+0.13\)). Using width, most eyes were prolate (294 eyes, 85%); and using height, the largest proportion of eyes was oblate (165 eyes, 47%). Eyes with longer ALs had greater widths, heights, volumes, and surface areas than eyes with shorter ALs \((P<0.001\) for all). With increasing AL, eyes became increasingly prolate. Children of less educated mothers had longer ALs \((P=0.02)\). Malay children had larger eye volumes and surface areas than Chinese or Indian children.

**Conclusions.** Most newborn Singaporean Asian children are born with prolate eyes. A longitudinal study is required to determine if globe shape at birth influences subsequent refractive changes.

Keywords: myopia, magnetic resonance imaging, neonates, image analysis

Myopia is an increasingly important public health problem, with particularly high rates amongst Chinese East Asian populations such as those in Taiwan and Singapore.1–3 Understanding the pathogenesis of myopia is important for formulating prevention strategies. Pathological myopia is associated with potentially blinding complications such as retinal detachment, choroidal neovascularization, and macular holes,4–6 and even less severe forms of myopia predispose to glaucoma and cataract in adulthood.7–9 Furthermore, the lifetime socioeconomic costs of myopia are considerable.9–11 Several risk factors for myopia in children have been identified in large-scale epidemiologic studies. These include a genetic basis for myopia susceptibility,12–14 and a diverse range of environmental factors such as near-work, outdoor activity, socioeconomic background, and nutrition.14–19 However, the pathogenetic mechanisms underlying myopia development remain poorly understood, with the relative contributions of genetic and environmental influences a key point of contention.

Myopia has traditionally been regarded as a mismatch between the refractive power of the eye and the length of the eyeball. However, it is increasingly being recognized that the anatomical deviations in myopia involve more complex three-dimensional (3D) changes than are captured in a single-dimension axial measurement.20–25 The shape of the eyeball is a variable that is increasingly being investigated with the advent
of high-resolution in vivo imaging techniques such as magnetic resonance imaging (MRI) and computer software for three-dimensional modeling. We have previously shown that the internal eye surface area increases with myopia in young children. Eye shape is different in myopic eyes compared to non-myopic eyes, even in its early stages. In myopic eyes, more myopic refraction is associated with an increasingly prolate shape due to greater axial elongation. In non-myopic eyes, more myopic or less hyperopic refraction is associated with roughly equal increases in length, width and height, indicating generalized enlargement of the globe.24 However, some basic questions concerning the variation of human eye shape remain unanswered.

There are no data on the distribution and variability of ocular dimensions and shape in the normal infant. Evaluating ocular dimensions and shape in infancy provides information on the baseline shape of the globe, before any environmental stimuli can have an effect. Race and a parental history of myopia have been associated with eye size and growth in children, but it is not known if these factors are correlated with ocular dimensions and shape at birth.26-30

The aims of this study are to determine the range and distribution of measures of eye size and shape, and to determine the associations between race and parental myopia with eye dimensions and shape, in newborn children.

METHODS

This study was conducted on a subset of the birth cohort study termed GUSTO: Growing Up in Singapore Towards Healthy Outcomes. This is Singapore’s largest and most comprehensive birth cohort study and is designed to adopt a life course approach to define the importance of fetal and developmental factors in early pathways to metabolic diseases.

The study population consists of the children of all pregnant women aged 18 years and above attending the first trimester antenatal dating ultrasound scan clinic at the two major public maternity units, namely National University Hospital (NUH) and KK Women’s and Children’s Hospital (KKH), in Singapore. These subjects are Singapore citizens or permanent residents who are Chinese, Malay, or Indian with homogenous parental ethnic background and have the intention to eventually deliver in NUH or KKH and to reside in Singapore for the next 5 years. Mothers on chemotherapy, psychotropic drugs, or with Type I Diabetes Mellitus were excluded. Only women who agreed to donate birth tissues such as cord, placenta, and cord blood at delivery were included. Out of the 3335 screened, 1163 (62% of the eligibles screened) pregnant women were recruited from June 2009 to September 2010.

A key feature of the GUSTO study is to have body fat measures on all participants. After delivery, the children of enrolled subjects underwent whole body MRI, including brain imaging, at 5 to 17 days to accurately document body fat.

Written informed consent from the parents of subjects was obtained. Most of the children had returned home by the time of the MRI, and many parents were unwilling to return to the hospital for the scan. Also, as we did not sedate the babies, many children who were unable to sleep through the scan had to be excluded. As such, only approximately 15% of the total cohort provided data for this study.

The study was approved by the Centralized Institutional Review Boards of the Singapore Health Services and Domain Specific Review Board (DSRB) of National Health Care Group.

MRI Acquisition and Eye Shape Analysis

Data Acquisition. At 5 to 17 days of life, neonates underwent fast spin-echo T2-weighted MRI (TR = 3500 ms; TE = 110 ms; field of view [FOV] = 256 mm × 256 mm; matrix size = 256 × 256; 50 axial slices with 2.0-mm thickness) scans using a 1.5-Tesla GE scanner (Signa 1.5T MR, GE Healthcare, Milwaukee, WI) with an 8-channel head coil at the Department of Diagnostic and Interventional Imaging of the KKH. Two T2-weighted images were acquired per subject. The image resolution was 1 × 1 × 2 mm³. The scans were acquired when subjects were sleeping in the scanner. No sedation was used and precautions were taken to reduce exposure to the MRI scanner noise. A neonatologist was present during each scan. A pulse oximeter was used to monitor heart rate and oxygen saturation throughout the entire scans. One-hundred eighty nine neonates underwent the T2-weighted MRI scans. Through visual inspection, 175 neonates with at least one good T2-weighted MRI scan were included in the analyses.

Segmentation. We developed an atlas-based segmentation approach to automatically delineate the left and right eyes from the T2-weighted image. We manually delineated the eye from one subject’s image. Segmenting the eye of other subjects was a matter of extrapolating from this manually labeled training image, referred as an atlas. This method is typically referred as atlas-based segmentation. It requires the use of image registration in order to align the atlas image to the other subjects’ images. We then constructed the 3-dimensional shape of the eye.31-33

3D Eye Coordinate System. We constructed a 3D coordinate system for each eye by determining the long, horizontal and vertical axes (Fig. 1). We fitted the eye shape using two spheres: one modeled on the corneal region and the other modeled on the vitreous humor. One sphere encompassed the whole of the corneal region and the other encompassed the whole of the vitreous chamber. We employed the least-square optimization method to fit the eyeball shape using these two spheres. The geometric center of the eye was then represented by the center of the sphere containing the vitreous humor. The long axis of the eyeball was defined as the line passing through the centers of the
The length, width, and height were measured automatically by the software. The traditional AL was computed as the distance between the most anterior and posterior points of the long axis, representing the length from the posterior corneal surface to the retinal surface. The vertical axis was then determined as the cross product between the long axis of the eye and the line passing through the centers of the left and right eyes. The cross product is a binary operation on two vectors in 3D space and results in a vector that is perpendicular to both of the vectors being multiplied and therefore normal to the plane containing them. The height of the eye was then calculated as the distance between the most superior and inferior points along the vertical axis. Finally, the horizontal axis of each eye was determined as the cross product of the long and vertical axes. The width of the eye was computed as the distance between the most temporal and nasal points along the horizontal axis. The length, width, and height described above were the measurements for the internal eye.

The term "globe" in this paper refers to the internal surface of the eye.

Eye Volume, Surface Area, and Shape Measurements. The volume of the eye was computed as the number of voxels labeled as part of the eye in the T2-weighted image multiplied by the image resolution, and the surface area of the eyeball was approximated as the area of the triangulated mesh.

We have used these scanning and analysis techniques in a previous study on older children. In that study, we evaluated the accuracy of the MRI segmentation by comparing the
longitudinal axial length obtained from MRI with the axial length using partial coherence interferometer (PCI), with no significant differences found.

**Statistical Analysis and Definitions**

A summary index of eye shape was given by oblateness, defined as $1 - (\text{axial length/equatorial diameter})$. Oblateness was determined using both the width and height as the equatorial diameter. A prolate eye was defined as oblateness $< -0.01$, while an oblate eye was defined as oblateness $> +0.01$. A spherical eye was defined as oblateness between $-0.01$ and $+0.01$.

The normality of the distributions of the various ocular parameters was assessed by plotting histograms and Q-Q plots, calculating skewness and kurtosis, and with formal tests of normality, including the Komolgorov-Smirnov one sample test. Mixed linear models were constructed to account for intereye correlations, with AL as the dependent variable and the other ocular measurements as the independent variables, with adjustments for mother’s race, mother’s age, mother’s education, gestational age, and parental myopia. Additional models were constructed with the ocular measurements as the dependent variables and antenatal factors as independent variables, adjusted for the same covariates as appropriate. Descriptive statistics was presented as the mean ($\pm$ standard deviation). All probabilities quoted were two-sided and all statistical analyses were undertaken using (SPSS 20.0; IBM Corporation, Armonk, NY).

**RESULTS**

A total of 346 eyes of 173 newborn children (5–17 days old) were included in the analyses. The mean gestational age at the time of MRI examination was 38.4 ± 1.1 weeks and the mean birth weight was 3125 ± 409 g.

Measurements were obtained from all the MR images. The mean AL, width, and height were 17.3 ± 0.9 mm (range, 14.0–19.6), 16.3 ± 0.8 mm (13.7–18.4); and 17.1 ± 1.0 mm (14.3–20.3), respectively, while the mean volume and surface area of the globe were 2428 ± 272 mm$^3$ (1653–3744) and 898 ± 70 mm$^2$ (677–1217), respectively. The mean oblateness in relation to width was $-0.06 \pm 0.05$ ($-0.23$ to 0.08), and the mean oblateness in relation to height was $-0.01 \pm 0.04$ ($-0.19$ to 0.15). Significance was found at $P < 0.05$.

**DISCUSSION**

Our study provides normative data on the ocular dimensions and shape in a cohort of newborn Asian children. Measurement of ocular dimensions and shape are normally distributed. The mean AL was 17.3 mm, comparable with that reported in other studies on newborn eyes. Axer-Siegel reported mean values of 16.6 ± 0.4 mm for right eyes and 16.5 ± 0.4 mm for left eyes in term infants, while Isenberg reported a mean value of 16.2 mm. The mean value at term reported by Fledelius in preterm infants, adjusted for an assumed average eye elongation of 0.14 mm per week, was 17.02 mm.

The advent of high-resolution MRI and computer software for 3D modeling has allowed for the direct study of eye shape in vivo. Cheng found that adult myopic eyes had the same shape as hyperopic or emmetropic eyes, with the width of the whole globe longer than the AL and height. Atchison studied the shape of the retinal surface in hyperopia and myopia, and found that both emmetropic and myopic retinas were oblate in...
shape.\textsuperscript{20} In another analysis of the internal dimensions of the eye,\textsuperscript{21} the same authors found that myopic eyes were elongated more in length but approximately equal proportions of myopic eyes fitted global expansion and axial elongation models exclusively. As described earlier, we have previously shown that axial internal globe enlargement occurs in myopic eyes leading to a prolate shape, whereas non-myopic eyes enlarge globally in length, width and height.\textsuperscript{24} In this study, we have shown that the shape of the eyeball is correlated with the axial length. Eyes with longer axial lengths have increasingly prolate profiles.

Data on globe shape in very young children is scarce. Ishii reported on the shape of the globe from MRI analyses in a cohort of 105 healthy patients with ages ranging from 1 month to 19 years undergoing routine imaging.\textsuperscript{25} Oblateness was calculated similarly, but a prolate shape was defined as oblateness < 0, an oblate shape as oblateness > 0, and a sphere as oblateness = 0. As in our study, AL was correlated with the oblateness of the eye. At age 0, the eyes were mostly oblate, with oblateness increasing with age. In contrast, using the same definitions of globe shape, most eyes in our study were prolate (90.2% using width to calculate oblateness, and 56.1% using height to calculate oblateness). However, the actual number of subjects with age 0 in Ishii’s study was very small (approximately 10–15 subjects). Our results suggest that most children are born with prolate globes. Newborn children are however usually not myopic.\textsuperscript{40,41} This suggests that, in newborn children, the other refractive components of the eye (e.g., lens) are more important determinants of refraction than eye shape. Longitudinal evaluation of the children in our cohort will allow us to determine if eye shape and size at birth are correlated with the subsequent development of ametropia.

This epidemiological association between parental myopia and myopia\textsuperscript{26,30} may be due to either genetic or environmental influences, and there is still no conclusive proof of either. In the Orinda Longitudinal Study of Myopia,\textsuperscript{27} Zadnik et al. performed a cross-sectional analysis of eye size and shape in relation to parental myopia in 662 nonmyopic children. After controlling for near work, children with two myopic parents had longer eyes and less hyperopic refractive errors than children with only one myopic parent or no myopic parents. However, in a study on 4,668 Chinese children performed in Hong Kong using similar methodology,\textsuperscript{42} although nonmyopic children with a stronger parental history of myopia tended to be less hyperopic before the onset of myopia, corresponding associations with AL did not follow the same pattern. Subsequent eye growth and the development of myopic refractive errors occurred more rapidly among children with a stronger parental history of myopia. In our study, parental myopia was not correlated with the size or shape of the eye at birth. However, we found an interesting association between lower maternal educational qualifications and longer globes in the offspring. Longitudinal evaluation to determine if these children with longer globes at birth subsequently develop myopia will help to shed light on whether myopia predisposition is congenitally determined.

Race has been associated with the prevalence of myopia in young children. In the adult population in Singapore, the Chinese have a higher prevalence of myopia than Malays and Indians.\textsuperscript{43,44} In our study, Malay children had larger globes (larger volumes and surface areas) than Chinese and Indian children, though this was only of borderline significance. This contrasts with the lower prevalence of myopia in adult Malay

homogeneity of eye shape at birth suggests that it may not
are associated with the size of the eye at birth. The
and that most newborn Singaporean Asian children are born
than we had. These are however nondifferential errors that
provide data on this population. The accuracy of our
measurements was partly limited by the acquisition time
afforded to us. General limitations include the cross-sectional
nature of our study which limits inferences of causation, and
the relatively small proportion of myopic children. Although
we did not systematically select a subset for analysis, there may
also have been unavoidable selection bias as only children
whose parents consented underwent MRI shortly after birth.
Most of the children had returned home by the time of the
MRI, and many parents were unwilling to return to the hospital
for their children to undergo the scan. Also, as we did not
sedate the babies, many children who were unable to sleep
through the scan had to be excluded. Other studies using MRI
to analyze eye shape have also had higher resolution images
through the scan had to be excluded. Other studies using MRI
for sedate the babies, many children who were unable to sleep
mri, and many parents were unwilling to return to the hospital
whose parents consented underwent MRI shortly after birth.
we did not systematically select a subset for analysis, there may
not affect the relationships we found.
In conclusion, our study has shown that the shape of the
newborn eye becomes increasingly prolate with increasing AL, and
that most newborn Singaporean Asian children are born
with prolate eyes. Race and maternal educational attainment
are associated with the size of the eye at birth. The
homogeneity of eye shape at birth suggests that it may not
influence subsequent refractive development, but a longitudi-
nal study is needed to confirm this.
