PURPOSE. We characterized the foveal avascular zone (FAZ) and the parafoveal capillary network in healthy subjects using swept source OCT optical microangiography (OMAG).

METHODS. We acquired OMAG images of the macula of 19 eyes (13 healthy individuals) using a prototype swept source laser OCT. En face images of the retinal vasculature were generated for superficial and deep inner retinal layers (SRL/DRL) in regions of interest 250 (ROI-250) and 500 (ROI-500) μm from the FAZ border.

RESULTS. The mean area (mm²) of the FAZ was 0.304 ± 0.132 for the SRL and 0.486 ± 0.162 for the DRL (P < 0.001). Mean vessel density (%) was 67.3 ± 6.4 for the SRL and 34.5 ± 8.6 for the DRL in the ROI-250 (P < 0.001), and 74.2 ± 3.9 for the SRL and 72.3 ± 4.9 for the DRL in the ROI-500 (P = 0.160).

CONCLUSIONS. Swept source OMAG images of healthy subjects allowed analysis of the FAZ and the density of the parafoveal capillary network at different retinal layers. Keywords: optical coherence tomography, angiography, image analysis, fovea, parafoveal capillaries

The fovea is the source of highest resolution vision. Its histological structure differs from the rest of the retina, with its inner retinal layers, including the capillaries, displaced from the photoreceptors to form the foveal avascular zone (FAZ).1 The FAZ is surrounded by a terminal capillary ring of side-branching retinal arterioles originating from the superior and inferior temporal branches of the central retinal artery.2 Elsewhere in the retina, capillary networks originating from the central retinal artery are located in different layers of the inner retina.3,4 The parafoveal capillary network and FAZ have been studied in vitro and in vivo, using various methods, including histologic techniques, high contrast enoptic view, fluorescein angiography (FA), and high-resolution imaging tools, such as adaptive optics and confocal scanning laser ophthalmoscopy.5–13 The introduction of phase variance optical coherence tomography (OCT) made it possible to visualize the retinal vasculature, including the capillaries with OCT technology.14 In particular, swept source (SS) ultrahigh-speed frequency domain OCT optical microangiography (OMAG) provides simultaneously high-resolution and three-dimensional information on the morphology of the retinal vasculature by capturing a series of B-scans in the same location, allowing isolation of motion (blood flow) signals from static (tissue) signals by image processing.15 The OMAG technique is a noninvasive, comfortable imaging method for the patient.

In the present study, we applied this novel, noninvasive imaging modality to characterize the FAZ and parafoveal capillary network in healthy subjects, and to compare our findings to those of previous studies on capillary visualization.

PATIENTS AND METHODS

A total of 13 healthy subjects participated in this study. Exclusion criteria included any evidence of ocular pathology or systemic disease. Informed consent was obtained from all subjects. The study protocol was approved by the Health Science Institutional Review Board of the University of Southern California and complied with the requirements of the Declaration of Helsinki.

Swept source OMAG images were acquired using a prototype SS laser OCT (510K clearance pending) from Carl Zeiss Meditec (Dublin, CA, USA) with a central wavelength of 1050 nm (1000-1100 nm full width), a speed of 100,000 A-scans per second, and a theoretical axial and transverse resolution of 5 and 15 μm in tissue. For SS-OMAG imaging, 3 × 3 × 3 mm macular cubes were acquired, with each cube consisting of 300 clusters of four repeated B-scans, each containing 300 A-scans. The time to acquire one cube was approximately 4.5 seconds. Clusters of four B-scans were taken to enable the visualization of motion when generating SS-OMAG images. An intensity differentiation algorithm was applied to extract in vivo blood vessel information as described previously.16 Before the algorithm was applied, displacement occurring between adjacent repeated B-scans caused by involuntary eye movement was compensated by a two-dimensional cross correlation between two adjacent flow images.17 Using this approach, we obtained detailed, depth-resolved images of the retinal vasculature in the posterior pole.
Corresponding en face projection images of the DRL. To delineate the best plane to separate the superficial and deep retinal capillaries, we first generated a rough estimate of the position of the outer border of the outer plexiform layer as approximately 110 μm internal to the retinal pigment epithelium. The automated algorithms used to estimate the position were based on existing segmentation techniques used in the Cirrus OCT (Carl Zeiss Meditec) to identify the retinal pigment epithelium and inner limiting membrane in the OCT intensity image.\(^\text{18}\) The neurosensory retina internal to this boundary was designated the inner retina and was divided further empirically into superficial (inner 60%) and deep (outer 40%) retinal capillary layers (SRL/DRL). En face images of the retinal vasculature were generated by a maximum intensity projection for the two identified layers. Generating the en face images took less than 10 seconds per cube.

Quantitative analyses were performed using the publically available GNU Image Manipulation Program GIMP 2.8.14 (available in the public domain at http://gimp.org). First, the area of the FAZ, defined by the area inside the inner border of the terminal capillary ring, was semiautomatically delineated by two independent graders for the SRL and DRL images (Fig. 1). Measures in pixels were converted to millimeters with intraclass correlation coefficients (95% confidence intervals) of 0.982 (0.938–0.994) for the SRL and 0.856 (0.668–0.942) for the DRL. The mean ± SD and percent differences were 0.182 (0.058) mm\(^2\) and 48.9% (18.2%), respectively, for the area of the FAZ, and 0.095 (0.029) mm and 25.0% (10.0%) for the effective diameter (paired \(t\)-test, \(P < 0.001\)). Measurements of the FAZ size were highly correlated between the two graders (intraclass correlation coefficients (95% confidence interval) of 0.982 (0.938–0.994) for the SRL and 0.856 (0.668–0.942) for the DRL. The mean ± SD and absolute

RESULTS

The mean (SD) axial length was 24.33 (0.92) mm.

Side-by-side inspection of images extracted from the SRL and DRL showed fewer visible vessels overall and larger central avascular areas for the DRL (Fig. 1). Table 1 shows the mean (SD) of the area and effective diameter of the FAZ, and the vessel density in the ROI for the SRL and DRL.

The mean size and effective diameter of the FAZ were statistically significantly smaller in the SRL compared to the DRL. The mean (SD) and percent differences were 0.182 (0.058) mm\(^2\) and 48.9% (18.2%), respectively, for the area of the FAZ, and 0.095 (0.029) mm and 25.0% (10.0%) for the effective diameter (paired \(t\)-test, \(P < 0.001\)). Measurements of the FAZ size were highly correlated between the two graders with intraclass correlation coefficients (95% confidence interval) of 0.982 (0.938–0.994) for the SRL and 0.856 (0.668–0.942) for the DRL. The mean ± SD and absolute

**FIGURE 1.** Swept source OCT optical microangiography images of two subjects centered on the fovea. (a, b) En face projection image of the FAZ (outlined) and the parafoveal microvasculature of the SRL. (c, d) Corresponding en face projection images of the DRL.

![Figure 2](image2.png)

**FIGURE 2.** Side-by-side comparison of en face projection and vessel extraction images of the SRL and DRL of the same eye. (a, c) En face projection image of the parafoveal vasculature of the SRL/DRL. The dashed white line shows the boundary of the FAZ. (b, d) Corresponding vessel extraction image of the SRL and DRL. The black outline shows the border between the ROI-250 and ROI-500.
mean differences in FAZ area measurements between the two graders were $-0.013 \pm 0.020$ and $0.014 \pm 0.019 \text{mm}^2$ for the SRL, and $0.014 \pm 0.086$ and $0.060 \pm 0.062 \text{mm}^2$ for the DRL.

The mean vessel density in the ROI-250 was statistically significantly greater in the SRL. The mean (SD) percent difference in vessel density was $32.8 (9.3, \text{paired} \ t\text{-test,} \ P < 0.001)$. In the ROI-500, there was no statistically significant difference in the mean vessel density when comparing the SRL and DRL (paired $t$-test, $P = 0.160$). The corresponding boxplot is shown in Figure 3.

**FIGURE 3.** Boxplot showing the vessel density in percent retinal area occupied by vessels for the ROI in the SRL and DRL. The ROI-250 was defined as the area within a distance of 250 $\mu\text{m}$ from the terminal capillary ring; the ROI-500 was defined as the area outside the ROI-250 within a distance of 500 $\mu\text{m}$ from the terminal capillary ring.

**DISCUSSION**

Ultrahigh-speed SS-OMAG can be used to produce detailed en face in vivo images of the FAZ and parafoveal vascular network noninvasively at different layers of the retina, suggesting that this technique may be used to study the vasculature of the central retina in healthy and diseased eyes.

The mean FAZ area and effective diameter in normal subjects corrected for axial length in this study (0.304 mm$^2$ and 0.544 mm for the SRL) were similar to results from previous studies using different modalities as shown in Table 2.

For example, using an adaptive optics scanning laser ophthalmoscope, Tam et al.$^{10}$ found an average vessel density of 31.6 mm$^{-1}$ ($N = 10$) in the inner region. In addition, using a high-resolution, wide-field dual-conjugate adaptive optics instrument, Popovic et al.$^{13}$ found a mean capillary density of 38.0 mm$^{-1}$ in the inner ROI and 36.4 mm$^{-1}$ in the outer ROI ($N = 5$). In both studies, measurements were corrected for ocular magnification. In a histologic study, Mendis et al.$^4$ found a mean vessel density of 41.1% in the superficial and 23.0% in the deep capillary network in confocal microscopy ($N = 5$). The specimens, however, were taken at 850 to 2150 $\mu\text{m}$ eccentricity from the foveal center. With FA, they found a mean vessel density of 24.4% in the same location ($N = 10$).$^4$

To convert their numbers to measures similar to those used by Tam et al.$^{10}$ and Popovic et al.$^{13}$, we could assume a capillary width of 7 $\mu\text{m}$. Their “capillary percent area” yields an area measurement that can be divided by capillary width to obtain total capillary length. Dividing total capillary length by the area of the ROI yields a metric that can be compared to other studies. Applying this algorithm, the measurements of Mendis et al.$^4$ convert to 58.6 and 32.9 mm$^{-1}$ in the superficial and deep layer by confocal microscopy, and 34.3 mm$^{-1}$ by FA. Our measures can be similarly converted using an estimated capillary width of 15 $\mu\text{m}$ to account for the apparent wider appearance of capillaries on OCT imaging. On our first assessment of the data, based on multiple measurements of the parafoveal capillaries in several images/cases, the average width appeared to be 15 $\mu\text{m}$, which corresponds to the transverse resolution of the SS-OCT system. Thus, based on the optical limitations, the use of an estimated capillary width of 15 $\mu\text{m}$ for our study appears appropriate. Using this assumption, our mean capillary density in the SRL converts to 44.9 mm$^{-1}$ in the ROI-250 and 49.5 mm$^{-1}$ in the ROI-500. In the DRL, the mean capillary density converts to 23.0 mm$^{-1}$ in the ROI-250 and 48.2 mm$^{-1}$ in the ROI-500. When compared to the results of Tam et al.$^{10}$ and Popovic et al.$^{13}$ our estimated vessel density is higher. This is most likely due to the different vessel extraction technique: Tam et al.$^{10}$ outlined the centerlines of the vessels, and Popovic et al.$^{13}$ skeletonized the vessel signature to a 1 pixel-wide tracing. In this study, the extracted vessel signature was not skeletonized as shown in Figure 2. When compared to the results of Mendis et al.$^4$, our estimated vessel density is lower for the superficial inner retinal layer.
This was expected as the specimens of Mendis et al.²¹ were taken at a greater eccentricity. Recently, Chui et al.²¹ used adaptive optics scanning laser ophthalmoscope imaging to study the relationship between the thickness of the retina and size of FAZ, and suggested that the inner retinal circulation might be required to support a retinal thickness greater than 60 μm.²¹ It would be interesting in the future with a larger cohort to determine whether a similar relationship could be established between retinal thickness and the OMAG determined FAZ.

Although the methods we used have many advantages, including the rapid and comfortable acquisition of the OMAG images, the depth resolution, excellent microvascular resolution, and the semiautomated analysis technique, there are several limitations to consider. These drawbacks include rare motion artifacts, low edge contrast of the vessels on the images, and the subjectivity of some of the assessments when determining vessel borders. Motion artifacts could be addressed by including faster eye-tracking to improve the image quality, especially in subjects with poor fixation/reduced visual acuity. The edge contrast limitation could be overcome by optimizing the postimage processing algorithms.⁴ An enhanced edge contrast of the vessels would likely increase the reliability of the measurements by facilitating the vessel border selection. With further improvements, a three-dimensional display and analysis of the vessel structure would make it possible to assess the vessel density proportional to the volume evaluated. A three-dimensional approach to study the vasculature is particularly important, since the division of the parafoveal capillaries into superficial and deep layers by OMAG imaging is somewhat arbitrary.

In summary, the FAZ and parafoveal capillary networks can be visualized noninvasively, three-dimensionally, and with high resolution using ultrahigh-speed SS-OMAG. In the present study, images acquired with this technique in healthy subjects allowed analysis of the FAZ and density of the parafoveal capillary network at different retinal layers. Selective visualization of the deep retinal capillary plexus, which cannot be accomplished by FA, is of particular interest as recent reports have identified diseases featuring isolated deep capillary ischemia.²² This suggests that this technique may be of great value to study the vasculature of the central retina in healthy and diseased eyes.
