Citation: Thompson A, Berry M, Logan A, Ahmed Z. Activation of the BMP4/Smad1 pathway promotes retinal ganglion cell survival and axon regeneration independent of mTOR and, therefore, may be of therapeutic interest.

Keywords: optic nerve crush, retinal ganglion cells, neuroprotection, laser capture microdissection, BMP4, Smad1

Axon regeneration in the adult mammalian central nervous system (CNS) is limited after injury by a multiplicity of factors, including a low intrinsic capacity of adult neurons to regrow their axons and the presence of myelin- and scar-derived axon inhibitory factors.1–5 However, intrinsic factors, such as cyclic adenosine monophosphate (cAMP), mammalian target of rapamycin (mTOR), and the repressors phosphatase and tensin homolog (PTEN) and suppressor of cytokine signaling 3 (SOCS3) promote CNS axon regeneration.6–9 The observation that mTOR activity is developmentally downregulated and new protein synthesis is suppressed after mTOR inactivation probably explains why some axons do not grow their axons and the presence of myelin- and scar-derived axon inhibitory factors.1–5 However, intrinsic factors, such as cyclic adenosine monophosphate (cAMP), mammalian target of rapamycin (mTOR), and the repressors phosphatase and tensin homolog (PTEN) and suppressor of cytokine signaling 3 (SOCS3) promote CNS axon regeneration.6–9 The observation that mTOR activity is developmentally downregulated and new protein synthesis is suppressed after mTOR inactivation probably explains why some axons do not normally regenerate in the mature CNS.10,11

Other pathways known to have a role in RGC axon regeneration include those activated by inflammatory stimulation, such as oncomodulin12–14 and activation of the JAK/STAT3 pathway,15–17 transcriptional repressors, such as Kruppel-like-factors (KLFs),18,19 Sox11,20 and c-Myc.21 However, the regenerative effects remain limited, since for example, activation of mTOR or overexpression of osteopontin and insulin-like growth factor 1 (IGF1) promotes selective regeneration of a small proportion of α-RGC that comprise only 6% of RGC in an intact retina.22 Therefore, other pathways must be identified to promote regeneration of a greater population of RGC.

One possible novel candidate therapeutic target is bone morphogenetic protein 4 (BMP4) and the downstream small mothers against decapentaplegic 1 (Smad1) signaling pathway that it activates. BMPs are essential in retinal development, upregulated after retinal injury, and activated downstream Smad1 signaling is neuroprotective for RGC.23–28 In addition, exogenous addition of BMP4 promotes the survival of RGC after NMDA-mediated damage,29 but RGC axon regeneration has not been studied after BMP4/Smad1 activation. However, in a conditioning lesion, where the peripheral branch of the dorsal root ganglia (DRG) is axotomized, Smad1 signaling is induced and is required for the enhanced axon growth potential, while a central axotomy failed to activate Smad1.30 Intrathecal injection of AAV-BMP4 to overexpress BMP4 in DRG neurons activated Smad1 signaling and promoted sensory axon regeneration after spinal cord injury in the mouse.31 Therefore, we reasoned that BMP4/Smad1 signaling might also be activated in RGC regenerating their axons and that intravitreal delivery of a BMP4 peptide may promote RGC survival and axon regeneration independent of mTOR and, therefore, may be of therapeutic interest.

RESULTS. In retinal cultures prepared from intact and ONC+PN-stimulated rats, RGC with neurites had upregulated regeneration-related and BMP4/Smad1 signaling pathway mRNA levels, while low levels of these mRNAs were present in RGC isolated without neurites. An optimal dose of 200 ng/mL BMP4 peptide in vitro promoted approximately 30% RGC survival and inhibited RGC neurite outgrowth, despite the presence of inhibitory CNS myelin extracts. BMP4 also promoted approximately 30% RGC survival in vivo and stimulated significant RGC axon regeneration at 100, 200, and 400 μm beyond the lesion site. Finally, the response of RGC to BMP4 treatment in vitro and in vivo was rapamycin-insensitive.

CONCLUSIONS. Activation of the BMP4/Smad1 pathway promotes survival and axon regeneration independent of mTOR and, therefore, may be of therapeutic interest.

Purpose. We investigate if the BMP4/Smad1 intracellular signaling pathway is neuroprotective and axogenic in adult rodent retinal ganglion cells (RGC) in vivo and in vitro.

Methods. Adult retinal cultures were prepared from intact and after optic nerve crush (ONC) injured rats that have been stimulated to survive and regenerate using an intravitreal peripheral nerve (PN) graft. Laser capture microdissection (LCM) then was used to isolate RGC with and without neurites. Quantitative RT-PCR determined changes in BMP4/Smad1 signaling pathway mRNA. Immunohistochemistry confirmed localization of BMP4 and activation of Smad1 in ONC+PN-stimulated RGC in vivo. BMP4 peptide was used to stimulate RGC survival and neurite/axon regeneration in vitro and in vivo. Finally, the rapamycin sensitivity of the effects was determined in BMP4-stimulated RGC in vitro and in vivo.
(ONC+PN)-treated retinal cultures and activity of the BMP4/Smad1 pathway investigated in RGC that grew neurites versus those that did not. In both RGC populations, signaling components of the BMP4/Smad1 pathway were highly active in RGC with neurites. BMP4 peptides disinhibited RGC neurite outgrowth in the presence of inhibitory CNS myelin extracts (CME) in vitro and promoted significant RGC survival and axon regeneration in vivo. Taken together, these results showed that BMP4/Smad1 could be a constituent of a neurotrophic factor cocktail required to promote RGC axon regeneration, thereby achieving greater RGC axon reconnection with denervated targets after visual pathway trauma and the reinstatement of visual function.

**METHODS**

**In Vitro Experiments**

**Experimental Design.** For the LCM studies, dissociated retinal cultures from \( n = 12 \) intact (uninjured) adult female Sprague-Dawley rats (170–220 g; Charles River, Margate, United Kingdom) were grown in triplicates (3 independent repeats, \( n = 9 \) wells/treatment) or adult Fischer rats (Charles River) prestimulated to grow by intravitreal sciatic nerve graft implantation (ONC+PN) for 21 days before harvesting retinae and dissociating retinal cells (\( n = 3 \) rats/experiment, three independent repeats, \( n = 9 \) wells/treatment) as described above (Figs. 1A, 1B).
Mixed Adult Rat Retinal Cultures. Retinal cultures were prepared from either intact 6- to 8-week-old Sprague-Dawley rats (180-220 g; Charles River) or 6- to 8-week-old Fischer rats (Charles River; to avoid SN graft rejection) at 21 days after ONC-PN implantation.52 Retinal cells were dissociated using a Papain dissociation kit and 125 μL per well.35 Pooled lentivirus cultures were incubated for 3 days at 37°C and 5% CO2.16

For LCM, dissociated retinal cells were grown on polyethyleneterephthalate (PET) membranes (Leica Microsystems, Milton Keynes, United Kingdom) coated with 10 μg/mL poly-L-lysine for 3 days in a humidified chamber. To stimulate neurite outgrowth, preoptimized NTF consisting of neurotrophin (NT)-3 (50 ng/mL), fibroblast growth factor 2 (FGF2; 10 ng/mL) and brain-derived neurotrophic factor (BDNF; 50 ng/mL; referred to as “combined NTF”) were used.35

To assess BMP4-mediated disinhibition of RGC neurite outgrowth, retinal cells were prepared from intact 6- to 8-week-old Sprague-Dawley rats (Charles River) as above and treated with increasing concentrations of BMP4 peptide (Peprotech) from 0-500 ng/mL in the presence of preoptimized CNS myelin extracts (CME).31,34 Retinal cultures were incubated for 3 days with the appropriate treatments before fixing in 4% paraformaldehyde in PBS (TAAB, Peterborough, United Kingdom) for 10 minutes at room temperature (RT) as described previously35 and subjected to βIII-tubulin immunocytochemistry and RGC neurite outgrowth analysis, as described above (Fig. 1A).

In Vivo Experiments. To confirm a role for BMP4, we injected three rats/group (three independent repeats; total 18 eyes/group) were used (Fig. 1B) to avoid graft rejection. Animals were assigned randomly to treatment groups of optimal concentrations of BMP4, allowed to set the background threshold levels for nonspecific staining before image capture.

RGC Neurite Outgrowth and Survival. The number of surviving βIII-tubulin+ RGC, those with neurites and the mean neurite lengths, were quantified at day 4 after plating and treatment as described by us previously.39 Briefly, the identity of chamber slides was masked by a second investigator and wells split into nine quadrants. Images were captured by the masked investigator from each quadrant using a Zeiss Axioscan 2 fluorescent microscope equipped with an Axiocam HRc and Axiovision software (all from Zeiss, Hertfordshire, United Kingdom). Negative controls had primary antibody omitted and were used to set the background and threshold levels for nonspecific staining before image capture.

LCM of RGC With and Without Neurites. Retinal cells were stained with fluorescent lipophilic dye FM1-43 (N[3-(triethylammoniumpropyl]-4-[4-(dibutylaminostyryl)pyridinium dibromide] (Invitrogen) for 20 minutes,34 fixed with 4% paraformaldehyde and 4% sucrose in PBS for 10 minutes, dehydrated through a graded series of ethanol and air-dried. An LCM microscope (Arcturus Pixcell II; Applied Biosystems, Rugby, United Kingdom) was used to isolate 1000 FM1-43+ RGC with and without neurites in each experiment and the RNA extracted, amplified, and quantitative (q)RT-PCR performed as described below. Experiments were repeated on three independent occasions.

In Vivo Experiments

Experimental Design. To assess the effects of intravitreal PN grafts on BMP4/Smad1 activation, three Fischer rats/group (repeated on three independent occasions; total n = 18 eyes/optic nerves/group) were used (Fig. 1B) to avoid graft rejection. Animals were assigned randomly to treatment groups and masked to the investigator. Groups included: (1) intact, (2) ONC, and (3) ONC-PN.

To assess activation of Smad1 after intravitreal BMP4 injection, three rats/group (three independent repeats; total
= 18 eyes/group) were used and included: (1) intact controls, (2) ONC+PBS (vehicle), and (3) ONC+BMP4 (5 μg BMP4 dissolved in a final volume of 5 μL PBS; dosage preoptimized to cause maximal RGC survival in vivo [not shown]). Animals received intravitreal injections of PBS or BMP4 immediately after injury and were killed at 7 days and prepared for immunohistochemistry for phosphorylated (p) Smad1 (pSmad1).

The effects of BMP4 on RGC survival and axon regeneration were studied in three rats/group (repeated on three independent occasions, total n = 18 eyes/ON/group) at 24 days after ONC and treatment; the groups included: (1) intact controls, (2) ONC+PBS (vehicle; to control for the effects of multiple intravitreal injections), and (3) ONC+BMP4 (5 μg BMP4; Fig. 1C). To assess if RGC axon regeneration promoted by BMP4 was rapamycin-sensitive (i.e., mTORC1-dependent), n = 3 rats/group (n = 18 eyes/ON/treatment); the groups included: (1) BMP4+/vehicle and (2) BMP4+/rapamycin. Rapamycin was prepared and administered as described previously. Briefly, rapamycin stock solutions were dissolved at 20 mg/mL in ethanol and, before each administration, diluted in 5% Tween 80. 5% polyethylene glycol 400 in PBS. Either rapamycin or vehicle was injected intraperitoneally immediately after ONC and every 2 days thereafter at a final concentration of 6 mg/mL.

ONC Group

All animal procedures were approved by the University of Birmingham local animal welfare and ethical review board and licensed by the UK Home Office. Surgery was done in strict accordance with the UK Animals Scientific Procedures Act, 1986 and the Revised European Directive 2010/63/EU according to the guidelines and recommendations for the use of animals by the Federation of the European Laboratory Animal Science Associations. Experiments also conformed to the ARVO Statement for Use of Animals in Ophthalmic and Vision Research except that bilateral ONC was enforced by the UK Home Office as a means of reducing animal numbers, in keeping with the 3R’s principle. Adult, female 6- to 8-week-old Sprague-Dawley or Fischer rats (according to experiment) were anesthetized using isofluorane inhalation and bilateral ONC and treatment; the groups included: (1) intact controls, (2) ONC+PBS (vehicle; to control for the effects of multiple intravitreal injections), and (3) ONC+BMP4 (5 μg BMP4; Fig. 1C). To assess if RGC axon regeneration promoted by BMP4 was rapamycin-sensitive (i.e., mTORC1-dependent), n = 3 rats/group (n = 18 eyes/ON/treatment); the groups included: (1) BMP4+/vehicle and (2) BMP4+/rapamycin. Rapamycin was prepared and administered as described previously. Briefly, rapamycin stock solutions were dissolved at 20 mg/mL in ethanol and, before each administration, diluted in 5% Tween 80. 5% polyethylene glycol 400 in PBS. Either rapamycin or vehicle was injected intraperitoneally immediately after ONC and every 2 days thereafter at a final concentration of 6 mg/mL.

Immunohistochemistry.

Eyes from perfusion-fixed animals were removed, cryoprotected through a graded series of sucrose solution and blocked in OCT (TAAB Laboratories, Berks, United Kingdom). Radial crosssections of eyes were adhered onto charged glass slides and immunohistochemistry (IHC) performed on sections thawed and washed in PBS. Nonspecific binding was blocked before incubation with the relevant primary antibody (Table 2) overnight at 4°C. Negative controls, including omission of primary antibodies were included in each run to set the background threshold before image capture. Sections then were washed in PBS, incubated with relevant secondary antibodies conjugated to either Alexa488 or Texas Red for 1 hour at RT, washed in further PBS and mounted using Vectashield containing DAPI (Vector Laboratories). Sections were examined using a Zeiss epi-fluorescent microscope attached to an Axiocam HRc and run using Axiovision software (all from Zeiss), with an experimenter masked to the treatment conditions.

Quantification of RGC Survival.

RGC survival was quantified as described previously. Briefly, sections containing the optic disc were selected from each eye and the number of RBPMs’ RGC were quantified along 250 μm lengths either side of the optic nerve head in four consecutive sections/retina.

Quantification of Müller Cell Activation.

Retinal Müller cell activation was quantified in glial fibrillary acidic protein

**RESULTS**

**LCM of RGC With Neurites Correlated With Increased Expression of Regeneration Related Genes**

LCM was efficient at targeted removal of cell bodies from RGC with and without neurites in naive retinal cultures treated with combined NTF (Fig. 2A). When RGC with and without neurites were compared, regeneration-related gap43, Sprr1a, c/ebp-epsilon, atf3, and galanin mRNA were 8-, 34-, 30-, 5.4-, and 10-fold upregulated in RGC with neurites, respectively, while SOCS3 mRNA levels remained unchanged (Fig. 2C). Analysis of components of the BMP4/Smad1 pathway in RGC treated with combined NTF in culture also showed that bmp4, smad1, smad4, smad5, smad8, smif, and msg1 mRNA were upregulated 3.2-, 4.5-, 5.5-, 2-, 3-, and 2-fold, respectively (P < 0.0001), in RGC with neurites compared to RGC without neurites (Fig. 2D). These results suggested that BMP4 that grow neurites in culture have a regenerative phenotype and upregulate genes in the BMP4/Smad1 pathway.

**LCM of RGC With Neurites 21 days After ONC+PN Correlates With Changes in Regeneration-Related mRNA**

After ONC+PN and subsequent culture of RGC, LRD injection into the distal segment of the optic nerve, beyond the ONC site, identified RGC that had regenerated axons through and beyond (Fig. 2E), whereas FMI-43 labeled all cells in culture, including RGC without neurites which were LRD− (Fig. 2F). There was a 15-, 40-, 35-, 12.4-, and 12-fold increase in regeneration-related gap43, Sprr1a, c/ebp-epsilon, atf3, and galanin mRNA, respectively, with no change in SOCS3 mRNA levels in RGC with and without neurites (Fig. 2G). These results are comparable with those seen in RGC treated with combined NTF (compare Figs. 2C and 2G), suggesting that a consistent profile of regeneration-related genes was switched on in RGC with neurites compared to RGC without neurites. The results also showed that some RGC survived for 21 days in vivo after ONC+PN, but did not grow their neurites when placed in culture.

Levels of mRNA for the BMP4/Smad1 pathway were significantly higher in cultured RGC that had been harvested 21d after ONC+PN treatment when compared to RGC in cultures prepared from naive eyes treated with combined NTF (Fig. 2H). For example, bmp4, smad1, smad4, smad5, smad8, smif, and msg1 mRNA levels were 15-, 24.5-, 25.5-, 9-, 10-, 12-, and 13-fold upregulated, respectively (P < 0.0001), in RGC with neurites compared to RGC without neurites (Fig. 2H). These results suggested that intact and ONC+PN-treated cultured RGC that grow neurites activate the BMP4/Smad1 signaling pathway.

**ONC+PN Activated the BMP4/Smad1 Signaling Pathway in RGC In Vivo**

Immunohistochemistry in intact control and ONC eye sections contained few IIH-tubulin+ RGC that also were BMP4+ (Fig. 2I). However, after ONC+PN treatment, many IIH-tubulin+ RGC were BMP4+ (Fig. 2I). Few IIH-tubulin+ RGC were phosphorylated (p) Smad1+ in intact controls (Fig. 2I), but after ONC, some IIH-tubulin+ RGC were pSmad1+, while after ONC+PN treatment, most IIH-tubulin+ RGC were pSmad1+ (Fig. 2J), indicating that the BMP4/Smad1 pathway was highly active in RGC regenerating their axons in vivo.

**BMP4 Peptide Promoted RGC Survival and Neurite Outgrowth on a CME Substrate**

Increasing concentrations of BMP4 peptide from 0 to 300 ng/mL increased the % IIH-tubulin+ RGC in retinal cultures to a maximum of 68% ± 7% (P < 0.0001) at 200 ng/mL, significantly greater than that observed in cultures without added BMP4 (32 ± 9%; Figs. 3A, 3D). The mean percentage of RGC with neurites and mean neurite length also increased in a dose-dependent manner to a maximum of 26 ± 3% (P < 0.0001) with 200 ng/mL and 238 ± 27 μm (P < 0.0001), respectively (Figs. 3B–D), despite the presence of inhibitory CME. These results suggested that BMP4 is a potent RGC survival and neurotrophic factor.

**Knockdown of BMP4 Receptors or Downstream Smad1 Abrogates BMP4-Induced RGC Survival and Neurite Outgrowth**

Approximately 70% knockdown of appropriate mRNA was achieved in RGC cultures treated with siBMPR1a (Fig. 4A), siBMPR1b (Fig. 4B), siSmad1 (Fig. 4C), and siACVR1 (Fig. 4D). Knockdown of BMPR1a, BMPR1b, ACVR1, or Smad1 in the presence of BMP4 peptide stimulation not only suppressed RGC survival to levels achieved with NBA alone (Fig. 4E), but also significantly inhibited RGC neurite outgrowth (Fig. 4F) in terms of percentage RGC with neurites (Fig. 4G) and the mean neurite length (Fig. 4H). These results suggested that inhibition of BMPR or Smad1 by siRNA block the survival and neurite outgrowth properties of BMP4 peptide.

Few, if any cells in the ganglion cell layer (GCL) were pSmad1+ in either intact retina or in retinae at 7 days after ONC+vehicle treatment (Figs. 5A, 5B), a time-point where there is some 20% to 40% RGC loss. However, intravitreal injection of BMP4 after ONC led to a significant increase in the number of ganglion cells with pSmad1+ immunoreactivity (Figs. 5A, 5B).

**Immunolabeling for pSmad1 (green) colocalized to βIII-tubulin+ (red) cells in the GCL (Fig. 5C; arrowheads), suggesting activation of the BMP4/Smad1 signaling pathway in RGC. The number of RBPM5+ RGC/mm at 24 days after ONC and treatment reduced from 61 ± 6 in intact controls to 5 ± 1 after ONC and vehicle treatment (Figs. 5D, 5E). BMP4 treatment promoted the survival of 16 ± 2 RGC/mm, equating to a significant increase in RGC of 31% compared to vehicle treated groups (P < 0.001). BMP4 also promoted a significant increase in the number of RBPMS+ RGC/mm at 24 days after ONC and treatment (Figs. 5D, 5E).**

**FIGURE 2.** Regenerating RGC upregulate BMP4/Smad1 signaling. LCM of (A) before and (B) after collection of RGC somata from FMI-43+ RGC with (red arrows) and without (white arrowbeads) neurites, stimulated by combined NTF (FGF2/BDNF/NGF). (C) Changes in regeneration-related mRNA in RGC (normalized to freshly isolated intact controls) with and without neurites and (D) in BMP4/Smad1 pathway. LCM of ONC+PN-stimulated regenerating (E) LRD+/FMI-43+ (red arrows) and nonregenerating (LRD-/FMI-43+; white arrowbeads) RGC showed similar changes in (G) regeneration-related mRNA in RGC with/without neurites compared to naïve retinal cultures. (H) Changes in mRNA levels of BMP4/Smad1 pathway molecules in regenerating and nonregenerating RGC prepared at 21 days after ONC+PN implantation mirrored that in intact control cultures except that levels of all mRNA were significantly higher. Immunohistochemistry to demonstrate (I) absence of BMP4 (red) in βIII-tubulin+ RGC (green) in intact or after ONC, but most RGC in the GCL were positive for BMP4 after ONC+PN treatment. (J) No pSmad1+ (red) immunoreactivity was localized in βIII-tubulin+ RGC (green) in intact eyes. However, some pSmad1+ RGC were present after ONC, but nearly all RGC in the GCL were positive for pSmad1 after ONC+PN treatment. (A, B, E, F) Scale bars: 50 μm, (I, J) Scale bars: 25 μm. **P < 0.01; ***P < 0.0001.
increase in GAP43+ axons present at 100 (P < 0.05), 200 (P < 0.003), and 400 (P < 0.05) μm beyond the lesion site compared to vehicle-treated groups in vivo (Figs. 5E, 5G). These data showed that BMP4 significantly enhanced RGC survival and axon regeneration in vivo.

The number of GFAP+ fibers crossing the IPL increased significantly to 16 ± 6 in vehicle-treated compared to intact eyes (Figs. 5H, 5I; P < 0.009). However, BMP4 treatment further increased the number of GFAP+ fibers crossing the IPL to 35 ± 2 compared to vehicle-treated eyes (Figs. 5H, 5I; P < 0.004) amounting to a 46% increase compared to vehicle-treated eyes. These results demonstrated that BMP4 treatment also activates retinal glia.

**BMP4-Stimulated RGC Neurite Outgrowth and Axon Regeneration was Rapamycin-Insensitive**

The addition of neither vehicle nor rapamycin (Fig. 6A) to optimal BMP4 peptide-treated retinal cultures (200 ng/mL) did not affect the levels of RGC survival (Fig. 6B), the percentage RGC with neurites (Fig. 6C), and the mean neurite length (Fig. 6D) in the presence of CME, suggesting that PI3K/mTOR/pS6 signaling was not involved in BMP4-stimulated RGC survival and neurite outgrowth (compare Figs. 6A-D with Figs. 5A–D). In addition, neither vehicle nor rapamycin affected BMP4-stimulated RGC axon regeneration in vivo (Figs. 5E, 5F). These results suggested that BMP4-stimulated RGC neurite outgrowth and axon regeneration are insensitive to rapamycin and, hence, mTORC1-independent.

**DISCUSSION**

The results of this study demonstrated that the BMP4/Smad1 pathway is highly active and correlates positively with RGC survival and neurite outgrowth/axon regeneration. BMP4 peptide addition in vitro and intravitreal delivery in vivo promoted significant disinhibited RGC neurite outgrowth and RGC survival and axon regeneration after ONC. In addition, delivery of BMP4 peptide in vivo promoted glial survival. Moreover, BMP4-stimulated RGC survival and neurite outgrowth and axon regeneration were insensitive to rapamycin and, hence, were mTORC1-independent. These results implied that activation of the BMP4/Smad1 pathway may be an additional target for therapeutic manipulation in the search for pan RGC axon regeneration.

Several studies have demonstrated that activation of the PTEN/mTOR pathway, usually by genetic deletion of PTEN or shRNA against PTEN,50,24,47,48 and codeletion of PTEN/ SOCS3,5 promotes the survival and regeneration of approximately 10% of all RGC in the murine retina.22 It seems apparent that no matter what the regenerative strategy in the optic nerve, only the ipRGC survive and regenerate their axons (i.e., <10% RGC).59,60 This is despite the multiplicity of neuroprotective/axogenic factors that includes mTOR activation (either deletion of PTEN or tuberous sclerosis complex 1 (TSC-1)),50,11 trophic factors derived from Schwann cells,59,51 macrophages,12,13 retinal glia,52,53 oncomodulin,12,14 and ciliary neurotrophic factor/leukemia inhibitory factor.17,54–56

In this study, we showed that the BMP4/Smad1 pathway was highly upregulated in RGC with neurites and also during RGC axon regeneration in vivo, suggesting that this pathway is an additional determinant of RGC neurite outgrowth/axon regeneration. BMPs constitute a large family of proteins and BMP signaling leads to phosphorylation of Smad1/5/8, which then forms a complex with Smad4, translocates to the nucleus, and regulates target gene expression.57,58 BMP has important functions during development of the nervous system, but BMP4 and BMP7 increase rapidly after spinal cord injury (SCI) in the rat, with phosphorylation of Smad1/5/8 at the lesion site.58–60 Moreover, overexpression of BMP4 in adult DRGN in vitro and in vivo activated Smad1 and enhanced the axon growth potential of DRGN in culture and after SCI in a mouse model.60

BMPs have essential roles in retinal development25–26,61 and BMP-Smad1/5/8 is neuroprotective for RGC since inhibiting BMP signaling reduces NMDA-induced RGC cytotoxicity.58 In addition, treatment with exogenous BMP4 promoted RGC survival after NMDA-induced damage.28 We also showed that exogenous BMP4 not only promoted significant RGC survival, but also promoted significant RGC neurite outgrowth. RGC growing neurites correlated with
significant activation of components in the BMP4/Smad1 pathway. In regenerating ONCþPN-treated eyes, we observed activation of BMP4 and pSmad1 in almost all RGC in the ganglion cell layer suggesting that BMP4/Smad1 signaling correlates with a regenerative RGC phenotype. Furthermore, BMP4 treatment in vivo promoted RGC survival, axon regeneration, and retinal glial activation. Moreover, BMP4-stimulated RGC neurite outgrowth/axon regeneration was insensitive to rapamycin, suggesting that the BMP4/Smad1 pathway is mTORC1-independent. Together these results suggested that BMP4/Smad1 is an additional signaling pathway, important in regulating non-ipRGC survival and axon regeneration. Our results agree with the observations made in adult DRGN in the spinal cord and suggested that reactivation of the BMP4/Smad1 pathway in adult CNS neurons can restore their axon growth potential.

It is clear that activation of the BMP4/Smad1 pathway stimulated RGC survival and axon regeneration (initiation and elongation). However, the pro-survival effect of BMP4 was small in scale and the morphology of surviving RBPMSþRGC in retinal cross-sections appear smaller and rounded compared to untreated control retinas. Therefore, it is possible that BMP4 delays the death of RGC and future experiments will need to address this question before BMP4 can be used therapeutically as a neuroprotective agent. Nonetheless, the regenerative response to BMP4 was rapamycin-insensitive and, hence, mTOR-independent, suggesting that the regeneration observed was probably in non-ipRGC. Although we did not determine the subtype of RGC responding to BMP4/

**FIGURE 4.** Knockdown of BMPR and Smad1 attenuates BMP4-stimulated RGC survival and neurite outgrowth. Confirmation of approximately 70% knockdown in (A) BMPR1a, (B) BMPR1b, (C) ACVR1, and (D) Smad1 mRNA in retinal cells by appropriate siRNAs. (E) Knockdown of BMPR and Smad1 significantly reduced RGC survival. (F) Representative images from siControl and siBMPR1a and siSmad1-treated wells. Knockdown of BMPR and Smad1 reduces (G) % RGC with neurites and (H) the mean neurite length. **P < 0.01; ***P < 0.0001, ANOVA. (F) Scale bars: 100 μm.
Smad1 activation, future experiments could address whether these constitute W3-RGC, M2-RGC, or ooDSGCs. It remains to be investigated if any of the other 30 subtypes of RGC are affected by BMP4 activation and, hence, the BMP4/Smad1 pathway presents itself as a valuable tool in determining the differential survival and regenerative responses of different RGC subtypes in the retina. Approximately 30% RGC survival was achieved after BMP4 treatment in vitro and in vivo with only 30% of those RGC growing neurites in culture and probably a similar small number also regenerating their axons in vivo. This suggested that RGC survival and axon regeneration are likely to be signaled differently and, hence, may require different combinations of neuroprotective/trophic factors. Indeed, we have shown that RGC exclusively activate cleaved caspase-2 after ONC injury and suppression of caspase-2 with a siRNA (siCASP2) protects >95% RGC in the rat retina. However, despite the survival of >95% of RGC, siCASP2 treatment did not cause RGC axon regeneration.

In conclusion, our results showed that the BMP4/Smad1 pathway is activated in surviving and regenerating RGC. Addition of exogenous BMP4 promoted non-ipRGC RGC survival and disinhibited neurite outgrowth/axon regeneration in vitro and in vivo, effects that were independent of mTOR signaling. Our results suggested that the BMP4/Smad1 represents an additional therapeutic target to achieve pan RGC survival and axon regeneration and, hence, restoration of lost function.
