Impact of cemeteries on groundwater contamination by bacteria and viruses – a review
Józef Żychowski and Tomasz Bryndal

ABSTRACT
In the process of decomposition of a human body, 0.4–0.6 litres of leachate is produced per 1 kg of body weight. The leachate contains pathogenic bacteria and viruses that may contaminate the groundwater and cause disease when it is used for drinking. So far, this topic has been investigated in several regions of the world (mainly Brazil, Australia, the Republic of South Africa, Portugal, the United Kingdom and Poland). However, recently more and more attention has been focused on this issue. This study reviews the results of investigations related to the impact of cemeteries on groundwater bacteriology and virology. This topic was mainly discussed in the context of the quantities and qualities of changes in types of microorganisms causing groundwater contamination. In some cases, these changes were related to the environmental setting of a place, where a cemetery was located. The review is completed by a list of recommendations. Their implementation aims to protect the local environment, employees of funeral homes and the residents living in the vicinity of cemeteries. In this form, this review aims to familiarize the reader with the results of this topic, and provide practical guidance for decision-makers in the context of expansion and management of cemeteries, as well as the location of new ones.

Key words | aquifer contamination, cemeteries, groundwater, interments, quality indicator microorganisms

INTRODUCTION
Cemeteries are among the chief anthropogenic sources of pollution and contamination of water in urban areas and beyond them (Silva et al. 2011). Many researchers are convinced that all cemeteries represent potential threats to the environment (Rodrigues & Pacheco 2005; Dent 2004). In the process of decomposition of a human body, 0.4–0.6 litres of leachate with a density of 1.23 g·cm⁻³ is produced per 1 kg of body weight (Silva 1995). The leachate contains 60% water and 30% salts in the form of ions containing nitrogen, phosphorus, Cl, HCO₃, Ca²⁺, Na⁺, compounds of various metals (e.g., Ti, Cr, Cd, Pb, Fe, Mn, Ni), and 10% of organic substances (Beak Consultants Ltd 1992; Silva 1998; Matos 2001; Żychowski 2008). This liquid is characterized by high conductivity, pH and biochemical oxygen demand (BOD) values, and by its specific fishy odour (Matos 2001). The contaminants come from the body and can include chemical substances applied in chemotherapy and embalming processes (e.g., arsenic, formaldehyde and methanol), makeup (e.g., cosmetics, pigments and chemical compounds), as well as various additional items, such as fillings, cardiac pacemakers, paints, varnishes, metal hardware elements, iron nails, etc. (Silva & Filho 2011; Fiedler et al. 2012). These leachates also contain microorganisms that may pollute substrates, surface water and groundwater. The microorganisms chiefly include bacteria, viruses, intestinal fungi and protozoa. They can also originate from other sources, e.g., animals, soil, water and the atmosphere (Trick et al. 2001).

The corpses of healthy humans and animals release bacteria, for example, those which form the group classified as total coliform bacteria: Escherichia coli, Enterobacter, Klebsiella, Citrobacter, Streptococcus faecalis, Clostridium perfringens, Clostridium welchii and Salmonella typhi, and
human-hosted viruses, e.g., enterovirus (Matos 2001; Dent et al. 2004; Castro 2008). In most cases, the contamination of the environment comes from pathogenic intestinal bacteria such as E. coli (Singleton 1999; Gleeson & Gray 2002), Pseudomonas aeruginosa (Knight & Dent 1998; Dent 1998, 2004), C. perfringens (Martins et al. 1991), and – in Brazil – even Salmonella spp. (Pacheco et al. 1991; Braz et al. 2000).

Most of these microorganisms accelerate the decomposition of organic matter and they are not pathogenic (De Ville de Goyet 1980). Many pathogens gradually die after the death of the host body as they are not capable of surviving for a long time outside of the host body, especially when environmental conditions are inappropriate (Gerba & Bitton 1984). These include, for example, Yersinia pestis, Vibrio cholerae, S. typhi, Mycobacterium tuberculosis, Bacillus anthracis, variola virus, hepatitis virus and HIV (human immunodeficiency virus) (Yates & Gerba 1983; Yates et al. 1985; Gerba et al. 1991; Healing et al. 1995; Üçisik & Rushbrook 1988; Cook 1993; Trick et al. 1999; De Ville de Goyet 2000; Matos 2001; Morgan 2004; Dent 2004). Therefore, some researchers (Bitton et al. 1983; Trick et al. 1999) have suggested that the groundwater contamination by bacteria and viruses in cemeteries results from contemporary pollutions. However, some microorganisms are long-living and, in appropriate environmental conditions, can survive in soil profile or in groundwater for some time, e.g., B. anthracis, variola virus and Clostridium spp. (Yates et al. 1985; Haagsma 1991; West et al. 1998). The survival period varies (Rudolfs et al. 1950; Romero 1970; Creely 2004). Lower temperature, higher soil moisture content associated with lower microbial activity, more alkaline environment, and higher organic matter content are the factors that extend the survival period of these microorganisms (Pacheco 2000), especially in the form of endospores. Creely (2004) states that the survival period of pathogens and saprophytes in the ground is limited to a maximum two to three years. In the case of V. cholerae this period is shorter and lasts approximately 4 weeks. However, some microorganisms can survive even up to 5 years and, in this time, they can migrate and reach the groundwater, e.g., E. coli (Rudolfs et al. 1950; Romero 1970). Usually, the migration time takes from 1 to 4 weeks (Pacheco 1986). Dent (2004) reported that in Australia this process may take up to 100 days. Some investigations suggest that this period may be extended to 6 to 8 months (Silva 1994).

Decomposition of interred bodies causes an increase in microbial activity in the surrounding substrate, associated with the release of persistent organic compounds (Matos 2001). Some of these organic compounds are highly toxic, e.g., putrescine (1,4-butanediamine) and cadaverine (1,5-pentanediamine) (Żychowski 2007; Castro 2008). These compounds can cause highly dangerous infectious disease such as liver inflammation (hepatitis C virus) and typhoid fever (S. typhi) (Dent 2000a, 2004; Bocchese et al. 2007; Leite 2009). Microorganisms associated with decomposition of interred bodies can also cause other diseases such as tetanus (Clostridium tetani), gaseous gangrene (C. perfringens), toxic contamination of food (E. coli), tuberculosis (Mycobacterium tuberculosis), paratyphoid fever (Salmonella paratyphi), bacterial dysentery (Shigella dysenteriae) and cholera (V. cholerae) (Silva, J. A. F. 2000; Silva, L. M. 2000; Josias & Harris 2004). It is worth emphasizing that bacteria transported by water, like those of the genus Shigella, as well as rotaviruses and protozoans of the genera Entamoeba and Giardia, often cause asymptomatic or serious infections with high mortality rates, particularly among children (Matos 2001).

A brief introduction indicated that cemeteries may have large adverse impacts on groundwater and can be a source of dangerous infectious diseases. So far, this topic has been investigated in several regions of the world (mainly Brazil, Australia, the Republic of South Africa (RSA), Portugal, the United Kingdom and Poland). Most of the studies are presented in Portuguese and for this reason have not yet reached worldwide attention. However, recently the international hydrological community has focused more and more attention on this issue. This study reviews the results of investigations related to the impact of cemeteries on groundwater contamination by bacteria and viruses. This issue was mainly discussed in the context of the quantities and qualities of changes in types of microorganisms causing the groundwater contamination. In some cases, these changes were related to the environmental setting of a place, where a cemetery was located. The review is completed by a list of recommendations. Their implementation aims to protect the local environment, employees of funeral homes and the residents living in the vicinity of cemeteries.

In this form, this review aims to familiarize the reader with the results of this topic, and provide practical guidance for decision-makers in the context of the location of new...
cemeteries, and the expansion and management of existing cemeteries.

CEMETERIES AND GROUNDWATER CONTAMINATION BY BACTERIA AND VIRUSES – REGIONAL OVERVIEW

Studies in Europe

The adverse impact of cemeteries on groundwater caught the attention of scientists at the end of the nineteenth century. In 1879, the French Society for Hospital Hygiene noticed the relationship between typhoid fever and groundwater contaminated by leachates from a cemetery in Paris (Migliorini 2002). This kind of adverse impact was also confirmed by Mulder in the summer of 1954 (Bouwer 1978). He found somewhat sweet-tasting water and an unpleasant smell exuding from wells situated close to cemeteries in Paris. A more serious consequence was the increased number of typhoid fever cases observed between 1963 and 1967 among people living around a cemetery in Berlin and using the groundwater from its vicinity (Bouwer 1978). In other studies carried out in West Germany in 1972, the groundwater of the alluvial substrate situated 0.5 m from burial sites showed quantities of bacteria 60 times higher than those found in natural water (Bouwer 1978). The quantities of these bacteria decreased rapidly to $8 \times 10^3$ CFU·100 ml$^{-1}$ (CFU, colony forming unit) at a distance of 3 metres from the interments, and to $1.8 \times 10^2$ CFU·100 ml$^{-1}$ at a distance of 5.5 m from the burial plots.

Contemporary research conducted in England within a nineteenth century cemetery in Nottingham, confirmed the occurrence of bacteria around burial plots (Trick et al. 1999). However, the general indicator of the total bacteria numbers at $1.38 \times 10^5$ CFU·100 ml$^{-1}$ in the groundwater did not indicate a hazard associated with the cemetery. Similar conclusions were voiced by Trick et al. (2001) with respect to the current Danescourt Cemetery in Wolverhampton (Table 1). In the groundwater of this cemetery they did find evidence of intestinal bacteria such as faecal streptococci ($S. \text{faecalis}$), Bacillus cereus, C. perfringens, Staphylococcus aureus and the thermotolerant coliforms. Neither the Salmonella spp., nor the enteroviruses and rotavirus were found. Relatively high levels of $S. \text{aureus}$ and faecal streptococci ($S. \text{faecalis}$) were recorded during long-lasting precipitation periods (Trick et al. 2001). $S. \text{faecalis}$ and thermotolerant coliforms probably originated from the ground surface. Bacillus cereus showed a great seasonal variation although it did not appear in all piezometers. In turn, C. perfringens was found along the groundwater run-off line from the cemetery (Trick et al. 2001). This bacterium is very resistant to adverse environmental conditions and, at favourable temperatures (15 to 45 °C), can proliferate under relatively high redox potential (Corry 1978).

In Portugal, extensive studies were conducted in three cemeteries: Querenc, Luz de Tavira and Seixas. In these places, Rodrigues & Pacheco (2003) found high numbers of, for example, $S. \text{faecalis}$, C. perfringens, faecal coliforms, heterotrophic and proteolytic bacteria. The samples were obtained from six boreholes and a well situated within an 800-m radius around the Querenc cemetery. The boreholes and the well were situated in karst structures. All samples contained bacteriological pollution (Table 2). However, the authors cited have not excluded a possible impact of septic tanks which were in use in the vicinity of this cemetery. This factor was also highlighted in Brazil (Carvalho & Silva 1997; Braz et al. 2000; Matos 2001).

High bacterial counts were also found in porous aquifers at the Luz de Tavira cemetery. The largest differences

between the samples taken from the cemetery and those from the reference site – a distance of c. 500 m – were related to heterotrophic and mesophilic bacteria, total coliforms and the bacteria of the genus Clostridium (Table 2).

The highest numbers of all the bacteria studied were found in the Seixas cemetery in Minho. The cemetery is located in a place where sea tides increase the thickness of the filtration layer. The samples from a borehole located in the central part of the cemetery contained decidedly higher quantities of bacteria than those from a borehole situated 290 m away from it.

Rodrigues & Pacheco (2003), on the basis of these studies, suggested that the climate of Portugal, where high precipitation and high air moisture occur in winter, is also a factor boosting bacteriological contamination of groundwater.

Studies in Poland concerned the impact of nine cemeteries and mass graves on the presence of B. cereus, S. aureus, Staphylococcus spp., C. perfringens, faecal streptococci (S. faecalis), Micrococcaceae and Entrobacteriaceae. Researchers from Europe (and some from the USA) drew particular attention to the occurrence at such sites of, for example, faecal streptococci (S. faecalis), P. aeruginosa and Clostridium spp. (Rodriguez & Bass 1985; Iserson 1995; Environment Agency UK 2002). It is worth mentioning that the researchers from the USA have not found faecal coliforms at cemeteries within their own country.

Studies conducted by the World Health Organization (Üçisik & Rushbrook 1988) concerning groundwater under cemeteries revealed the presence of B. cereus, faecal streptococci (S. faecalis), Micrococcaceae and Entrobacteriaceae. Researchers from Europe (and some from the USA) drew particular attention to the occurrence at such sites of, for example, faecal streptococci (S. faecalis), P. aeruginosa and Clostridium spp. (Rodriguez & Bass 1985; Iserson 1995; Environment Agency UK 2002). It is worth mentioning that the researchers from the USA have not found faecal coliforms at cemeteries within their own country.

**Studies in South America**

Studies focusing on groundwater quality in cemeteries were mainly developed in Brazil. Bergamo (1954) was the first to draw attention to the impact of cemeteries on the groundwater and surface water contamination in cemeteries and beyond them. During the Fourth Inter-American Congress of Sanitary Engineering in São Paulo, he emphasized the need for geological research and delineation of zones at risk of contamination around cemeteries. Since the early 1980s, these studies have been developed by Professor A. Pacheco at the Centre of Underground Water Research at the University of São Paulo, supported by the Institute of Biomedical Sciences at the same university (Costa et al. 2002). His first study covered 22 cemeteries in São Paulo (Pacheco 1986). In this study, he focused on the impact of public cemeteries on the environment and suggested that geological, geotechnical and hydrogeological studies
should precede decisions concerning localization of new cemeteries. He also emphasized the need to protect surface and underground water near cemeteries, so that the water could still be used for drinking (Miotto 1990).

Most of the Brazilian studies confirmed the adverse impact of cemeteries on bacteriological contamination of the groundwater. The main results of these studies are briefly presented below.

**The Vila Nova Cachoeirinha, Vila Formosa and Areia Branca cemeteries**

The studies conducted by Pacheco’s team in three Brazilian cemeteries, Vila Formosa and Vila Nova Cachoeirinha in São Paulo and Areia Branca in Santos, confirmed the presence of bacteria in all samples (Pacheco et al. 1991). However, the quantities of the bacteria found were not high in any of them.

Samples collected in Vila Nova Cachoeirinha contained mainly proteolytic, heterotrophic, lipolytic bacteria and faecal coliforms (Table 3). When the numbers of these bacteria were high, the samples exuded an insipid smell. It should be mentioned that many of these pathogenic bacteria, e.g., *Pseudomonas* and *Bacillus*, are good indicators of contaminants originating from graves, because they decompose proteins and lipids (Higgins & Burns 1975; Martins et al. 1991; Matos 2001).

These authors also found other indicators of contamination, e.g., total coliforms, thermotolerant coliforms, *S. faecalis* and sulphite reducer clostridia. In one case, they even confirmed the presence of *Salmonella*. The thermotolerant coliforms and total coliforms also showed higher numbers in all samples collected from four out of five wells within the Santa Inês Cemetery in Espírito Santo state (Neira et al. 2008).

The subsequent studies (Matos & Pacheco 2000, 2002) at the same cemetery (Vila Nova Cachoeirinha) also revealed that samples of groundwater mainly contained heterotrophic and proteolytic bacteria, *C. perfringens*, as well as enteroviruses and adenoviruses (Table 4). These studies demonstrated, however, the low levels of total and faecal coliforms in the groundwater (Matos & Pacheco 2000).

In his voluminous PhD dissertation, Matos (2001) confirmed the high maximum numbers of many bacteria (Table 3). It is worth mentioning that heterotrophic bacteria (being aerobic bacteria) are good indicators for detecting contaminants originating from graves. They are not pathogenic but may pose a hazard to health when high quantities occur.

The groundwater of these three cemeteries (Vila Formosa, Vila Nova Cachoeirinha, Areia Branca) was also investigated by Martins et al. (1991). Pacheco’s investigations

(Pacheco et al. 1999) were performed at almost the same time as those of Martins et al. (1991). Martins’ team analysed 67 groundwater samples. Most of the samples contained higher quantities of S. faecalis and sulphite reducer clostridia compared with the faecal coliforms (Table 5). The presence of coliphages was not confirmed (Martins et al. 1991). The authors suggested that S. faecalis and sulphite reducer clostridia content are more appropriate indicators for evaluation of the sanitary conditions of the cemetery groundwater. In this study the Salmonella spp. were detected in one of the 44 analysed samples. However, the occurrence of these dangerous bacteria, with a maximum of 3,000 CFU-100 ml \(^{-1}\) (determined by the membrane filter method), was confirmed by Final (2007) in two cemeteries: São Gonçalo and Parque Bom Jesus in the Cuiabá region of Mato Grosso state.

Among the cemeteries (Vila Nova Cachoeirinha, Vila Formosa, Areia Branca) the worst quality of groundwater was recorded at the Areia Branca cemetery in Santos (Table 5).

According to Pacheco et al. (1991), diversity in the numbers of bacteria in cemeteries’ groundwater is associated mainly with varying lithological conditions as well as the depth of the groundwater table. Similar conclusions were formulated by Martins et al. (1991) and Matos (2001). The poor quality of the groundwater at the Areia Branca cemetery in Santos is associated with the permeable sandy formations (Quaternary age marine sediments) and shallow groundwater table – c. 2.2 m below the terrain surface (Martins et al. 1991). The environmental settings of the remaining two cemeteries in São Paulo are slightly different. The groundwater table is significantly deeper and reaches, on average, 12.0 m below the terrain surface (Bastianon et al. 2000). The substrate of the Vila Formosa cemetery is mainly composed of alternating layers of clays and sandy clays of Tertiary age sediments (Migliorini 1994). In turn, in the Vila Nova Cachoeirinha cemetery, the substrate is mainly composed of sandy sediments containing clayey layers. These clayey layers are acidic and contain few organic substances. As a result, they are not very active in terms of ion exchange (Matos et al. 2002). The authors even emphasized hydraulic conductivity of the substrate. Clayey substrates are less permeable to a cemetery’s

effluents. In this way they limit a cemetery’s impact on the bacteriological contamination of the groundwater. The large influence of this factor was also confirmed in the studies at the Vila Rezende cemetery in Piracicaba, where hydraulic conductivity amounted to $6.5 \times 10^{-7}$ cm·s$^{-1}$ (Silva et al. 2011).

It should be noted that those investigations contributed to the development of a method enabling evaluation of susceptibility of the groundwater to bacteriological contamination. The GOD method (an abbreviation of Groundwater hydraulic confinement; Overlying strata; Depth to groundwater table) suggested by Foster et al. (2006) was used to estimate the susceptibility to contamination of groundwater at four cemeteries in Santa Maria in the state of Rio Grande do Sul (Kemerich et al. 2010). The results revealed that the method may be very useful for the evaluation of the bacteriological contamination hazard in cemeteries and their vicinity.

Finally, it is worth presenting an investigation concerning the migration of bacteria, performed by Matos (2001) in the Vila Nova Cachoeirinha cemetery. The studies revealed that bacteria may migrate over a distance of several metres beyond the cemetery. The number of bacteria decreased as the distance from the interments increased. Viruses turned out to be more mobile than bacteria, moving tens of metres. The viruses were also transported at least 3.2 m through the unsaturated layer and reached the groundwater layer. These investigations also revealed that the highest contamination occurred at those places where the graves were close to the water table, the graves were not older than one year and the graves were situated in the low-lying parts of the cemetery.

The effect of shallow groundwater table on the high bacteria content, mentioned by Pacheco et al. (1991), Martins et al. (1990) and Matos (2001), was also confirmed in research conducted in two cemeteries: da Paz and da Saudade in Belo Horizonte in the state of Minas Gerais by Costa et al. (2002) and in two necropoli (São Gonçalo and Parque Bom Jesus) in the Cuiabá region of the Mato Grosso state (Final 2007). In all of these four cemeteries the groundwater quality was unsatisfactory. No presence of E. coli was found in these cemeteries. In general, however, in all these four cemeteries, the quality of groundwater was unsatisfactory. Of particular concern is the maximum number of thermotolerant coliforms – $2.4 \times 10^{6}$ CFU·100 ml$^{-1}$ in a sample collected from a low-lying place. It is worth emphasizing that thermotolerant coliforms are rarely recorded near places of burial (Martins et al. 1999). This fact results from their shorter survival time in the soil and groundwater compared with other bacteria of the coli group.

The Itaquera cemetery

Studies at the Itaquera cemetery (Silva et al. 2008) revealed the presence of total coliforms and bacteria classified as Shiella and Klebsiella spp., capable of causing diarrhoea. The high level of groundwater contamination was explained by: (1) location on a steep slope (40%); (2) sandy-clayey bedrocks with suspended aquifer, covered by an impermeable layer of red lateritic loam; (3) lack of a sewage system at the cemetery; (4) lack of management plans at the cemetery; (5) leaking tombs and graves; (6) faults in grave construction; (7) faults in the interment procedures; and (8) lack of appropriate collection and utilization of the solid waste from the cemetery. Such conditions were conducive to ground erosion and landsliding that even predisposed groundwater contamination. In addition, a distance of less than 50 m to the nearest building estate also had an adverse impact on the quality of water. All these factors contributed to the conclusion that the location of the Itaquera cemetery in São Paulo was unfavourable.

The São José cemetery

The elevated numbers of bacteria: heterotrophic – up to $300 \times 10^{2}$ CFU·100 ml$^{-1}$, total and faecal coliforms – up to $8 \times 10^{3}$ MPN·100 ml$^{-1}$ (MPN, most probable number), and faecal streptococci (S. faecalis) – up to 235 CFU·100 ml$^{-1}$, were also confirmed at the São José cemetery in Belém in Pará state (Braz et al. 2000). The faecal coliforms and faecal streptococci were not found in a control artesian well. However, significant contamination of the groundwater by faecal and total coliforms (up to $13 \times 10^{3}$ MPN·100 ml$^{-1}$) occurred in the well below the cemetery, as well as in a stream flowing c. 100 m from the cemetery boundary. This small stream acts as a water-collector for the surface water from the cemetery. Some contamination may even come from neighbouring households (Braz et al. 2000). High groundwater
contamination was also boosted by permeable, vulnerable-to-pollutants Tertiary age outcrops made of fine- and medium-grained sands.

The Várzea cemetery

In the Várzea cemetery in Recife, Espindula & Santos (2004) collected samples from three piezometers and five wells. They were located within and beyond the cemetery, at distances ranging from 6 to 110 m from the cemetery boundary. He found *P. aeruginosa* in all samples, with numbers ≥1,600 MPN/100 ml. Remarkable quantities of *P. aeruginosa* were confirmed by other researchers in individual wells (Martins et al. 1991; Vasconcelos et al. 2006). It should be emphasized, that this bacterium inhibits the growth of total coliforms (CETESB 1996; Guilherme & Silva 1998; Almeida et al. 2006). Therefore, these bacteria were not found (Table 3).

In this cemetery, water from the piezometers also contained heterotrophic and proteolytic bacteria, as well as sulphite reducer clostridia (Table 3). High numbers of these bacteria, particularly the proteolytic types, provided the evidence that higher quantities of microorganisms appear, especially in the piezometers situated near the graves less than one year old (Almeida et al. 2006).

In the Várzea necropolis, the clastic substrates, where the graves were located, are up to 8 m in thickness. Unfortunately, these sediments have high permeability due to their lithology, composed to a depth of 3 m of sands, silts and loams; from 3 m to 6 m of poorly graded gravels; and below 6 m of sands. Moreover, the groundwater table fluctuates in the range of 2.9–9.5 m below terrain surface (Espindula & Santos 2004; Almeida et al. 2006). The contamination is facilitated by mostly shallow graves with coffins placed directly into the ground at depths ranging from 0.6 to 0.8 m (Santos & Espindula 2005). At the time when this necropolis was studied, there were 3,519 graves on an area of 2.2 ha.

The Santo Amaro cemetery

Studies at the Santo Amaro cemetery in Campo Grande in Mato Grosso do Sul state (Abrão 2007) revealed higher numbers of heterotrophic and proteolytic bacteria. At this site, *C. perfringens* and total coliforms occurred only in two wells (Table 3). In one well higher numbers of *S. faecalis* and *E. coli* were also found (Table 6). These wells were situated in the middle and lower parts of the slope. According to a cautious opinion expressed by Abrão (2007), such a contamination of the groundwater could be linked to the decomposition of corpses during the period of the studies. At that time, there were 24,000 graves on an area of 27.3 ha. The contamination could also be increased by shallow graves with depths ranging from 1.70 to 2.50 m. The corpses were also buried sporadically on three levels. According to Abrão (2007), the groundwater level is shallow there, ranging between 5.65 and 12.50 m. This diversity results from the cemetery being situated on an upland slope of a basaltic cuesta, descending gently from an elevation of 597.50 to 585.77 m.

above sea level. The infiltration of relatively high rainfall, c. 1,500 mm per year in a tropical climate, is facilitated by the considerable proportion of sand in the substrate (44% sand, 31% loam and 25% silt). This is indicated by a high permeability coefficient which ranges from 5 to 10 cm·s⁻¹.

The studies presented so far emphasized the adverse impact of cemeteries on the groundwater quality in their surroundings. According to Silva, L. M. (2000) 75% of 600 cemeteries in Brazil pollute the environment. However, some Brazilian research has revealed that the influence of cemeteries on groundwater contamination is less noticeable. This fact was confirmed in the studies conducted on a newly founded but closed municipal cemetery in Parque Bom Jardim on Estrada Jatobá street in Fortaleza in Ceará state (Sousa et al. 2008). In contrast to the previously discussed cemeteries, this cemetery was established on clays and silts. In such environmental settings, average velocity of the groundwater flow (calculated on the basis of monitoring the contamination in nine piezometers), reached 0.27 m per day. The study revealed that the zone of groundwater contamination around the border of the cemetery did not exceeded 13.5 m and time of migration took up to 50 days (Sousa et al. 2008). It is worth remembering that in fine-grained sediments the biological contaminants may migrate up to 30 m (Romero 1970).

The influence of limited infiltration in clayey sediments on the biological contamination of the groundwater was also confirmed by Oliveira et al. (2002). They noted an increasing biodegradation of organic matter and elimination of bacteria in substrate downward of the vertical profile. This phenomenon occurred in the moist tropical climate in the Domini Max II cemetery, in the Belém region in Pará state.

No negative impact on the groundwater was demonstrated in the study carried out by Mello et al. (1995) on a contemporary cemetery at da Paz in São Paulo. The study did not confirm the presence of faecal coliforms, faecal streptococci (S. faecalis), sulphite reducer clostridia, coliphages and Salmonella in the groundwater collected from two wells near the graves. There were only small numbers of heterotrophic bacteria and total coliforms.

The preliminary studies conducted at the Santana cemetery, on the Ilha de Maré island in Salvador in the state of Bahia (Leite 2009), confirmed that groundwater was polluted by total coliforms and thermotolerant coliforms (c. 200 CFU-100 ml⁻¹). However, the author concluded that the contamination did not exceed the norms (Leite 2009).

Worthy of mention is that some Brazilian researchers have doubts concerning the negative impact of cemeteries on groundwater quality in the vicinity of these areas. According to Espindula (2004), the increased quantities of total coliforms and the presence of faecal coliforms or thermotolerant coliforms in two household wells near the Várzea cemetery in Recife, can be also connected to other factors, e.g., leaky sewage systems. Similar doubts have also been raised by other researchers (Mello et al. 1995; Carvalho & Silva 1997; Braz et al. 2000; Matos 2001; Almeida et al. 2006; Sousa et al. 2008; Leite 2009). Almeida et al. (2006) found relatively low levels of contamination in a household well near the cemetery compared with a more distant well. In their opinion, this finding resulted from other factors, including additional sources of pollution, such as the lack of sewage systems or their leakages, the conservation and cleanliness of the well, the type of aquifer in use, and the rainfall amounts.

These arguments may suggest that investigation focusing on groundwater contamination by bacteria and viruses must take into account additional factors not directly related to the cemeteries, e.g., spatial distribution of the sewerage system and its condition, etc.

Studies in Africa

Studies carried out in South Africa revealed that the localization of many cemeteries was incorrect. Significant microbiological contamination of groundwater was found by Engelbrecht (1993) in a municipal cemetery in the Western Cape Province (Table 3). He evaluated the water quality on the basis of 20 wells situated within the cemetery, one well located at 50-m distance, and a reference (control site) municipal well 500 m away from the cemetery (Engelbrecht 1993). The wells, set in sands, showed high quantities of E. coli (5.7 × 10⁵ CFU·100 ml⁻¹), S. faecalis (205.0 × 10⁵ CFU·100 ml⁻¹), S. aureus (5.4 × 10⁵ CFU·100 ml⁻¹), heterotrophic bacteria and faecal coliforms (Table 3).

High groundwater contamination was also diagnosed at Ditengteng cemetery in Tshwane (Tumagole 2006). In samples collected from several wells situated in their vicinity, high levels of several microbiological parameters (e.g., total
coli,
faecal coliforms and a number of heterotrophic bacteria) were found (Table 3). Moreover, Tumagole (2006) found *E. coli* in two samples. These bacteria occurred in shallow groundwater in an unconfined sandy aquifer and in the coastal zone. The level of the groundwater increases during the rainy season in Tshwane. As a consequence, the contamination of the environment by microorganisms originating from the cemetery takes place (Tumagole 2006).

Total and faecal coliforms were also found in groundwater in the urban Granvilleille cemetery in Harare, Zimbabwe (Tumagole 2006). These results were obtained in seven piezometers situated at the cemetery itself, and downslope, and compared to a control site.

African researchers are of the opinion that the biological contamination of groundwater at the African cemeteries are associated with: (1) the number of burials; (2) the physical, chemical and biological properties of the natural environment; (3) fluctuations of the groundwater table; (4) circulation of the groundwater in the substrate; and (5) the ability to create binding between decomposition products and the substrate, and organic matter (Wright 1999).

**Studies in Australia**

A smaller impact of cemeteries on the groundwater contamination was found in Australia. Two series of studies by Dent (1995, 2005) carried out at the Botany cemetery in Sydney revealed low levels of bacteriological contamination. The groundwater was polluted by total coliforms, *S. faecalis*, faecal coliforms and *P. aeruginosa* (Table 6). These microorganisms were found in piezometers situated along the line of water runoff, particularly below new graves, in four out of 11 boreholes (Dent 2005).

Dent (2000a) also reported increased quantities of microorganisms: faecal coliforms (*E. coli*), faecal streptococci (*S. faecalis*) and *P. aeruginosa* in the vicinity of graves at the Botany cemetery in Sydney, and at the Guildford cemetery in Perth (Table 6). The number of bacteria decreased rapidly with a growing distance from the graves. According to Knight & Dent (1998) and Dent (2000a) the migration of microorganisms in these cemeteries is hampered by the lithology of substrate. In Sydney, the substrate is composed of sandy clays and a clayey mantle of sandstone (Knight & Dent 1998). The cemetery in Perth is located on shallow marine sediments of Holocene age, composed of clayey and silty sands, and fine sands (Dent 2000a). A considerable reduction of the decomposition products may also result from the activities of naturally occurring microorganisms not associated with interments, e.g., with iron bacteria, and also sulphur bacteria of the genus *Thiobacillus* (Knight & Dent 1998).

The importance of hydrogeological conditions was also confirmed by studies carried out in the Cheltenham cemetery in Adelaide. This cemetery is above an aquifer of the Adelaide Plain (River Torrens Fan of the Lower Outwash Plain), Pooraka Formation, with a phreatic surface between 4 and 4.7 m below the terrain surface. The substrate is composed of silty and sandy clays, silty clayey sands and minor silty sandy lenses, the latter probably representing channel fills. In this case, the depth of the groundwater table (4.0–4.7 m) was considered a factor that restricted groundwater contamination (Knight & Dent 1998). In spite of these good hydrogeological conditions, a pathogenic bacterium *P. aeruginosa* was found in the groundwater. Moreover, higher quantities of total coliforms were found (Table 6).

The unconsolidated but firm clays up to 10–12 m thick that overlie sandy silts and silty sands of the Brighton Group formations at the Necropolis cemetery in Melbourne also did not appear to constitute an efficient barrier (Dent & Knight 1998). Even though the aquifer was sampled at a depth ranging from 14 to 28 m, the researchers found the presence of several groups of bacteria: total coliforms, *S. faecalis* and faecal coliforms (Table 6). Their numbers varied considerably over time. Additionally, in three wells situated at the cemetery, the bacteria classified as total coliforms were found in quantities ranging from $2.4 \times 10^3$ to $3 \times 10^3$ CFU·100 ml$^{-1}$. The numbers of *E. coli* and *S. faecalis* were significantly higher (Table 6). Their numbers decreased rapidly with distance from the cemetery. Dent & Knight (1998) regarded that the presence of all decomposition products in the groundwater resulted from water seeping into the wells at a depth of 2.5–5.5 m below the terrain surface. Some contamination might come from the decomposition of coffins and embalming substances.

The studies carried out by Dent in Australia (2000b, 2004) revealed low levels of bacteriological groundwater pollution in a moderate climate condition. Irrespective of the bedrock settings, most of the microorganisms did not migrate
in the southern part of Africa, the increases were recorded with respect to all microbiological indicators (Table 3), namely, total coliforms, faecal coliforms, heterotrophic bacteria, faecal streptococci, E. coli and S. aureus (Fisher & Croukamp 1993; Engelbrecht 1998; Tumagole 2006). One of the highest contamination levels was diagnosed in the Western Cape cemetery in the Republic of South Africa, situated in loose sands (Engelbrecht 1993). Such a substrate is particularly conducive to contamination (Martins et al. 1991; Braz et al. 2000; Rodrigues & Pacheco 2003; Almeida et al. 2006; Zychowski 2009; Silva et al. 2011).

Many authors noted the occurrence of P. aeruginosa at the cemeteries in Brazil (Pacheco et al. 1991; Espindula 2004) and in Australia (Knight & Dent 1998; Dent 2005; Dent & Knight 1998).

Thermotolerant coliforms were often absent from the vicinity of interments (Martins et al. 1991). This results from their shorter survival time in the soil and groundwater, compared with other bacteria from the coli group. These bacteria were most often reported in samples taken from low-lying places at contemporary cemeteries in Brazil (Final 2007; Neira et al. 2008). They were also reported during rainfall periods at cemeteries in England (Trick et al. 2001).

The largest quantities of E. coli (Abrão 2007) were noted in Brazil. Small amounts were found in Australia, in the Necropolis cemetery in Melbourne, in the Woronora and Botany cemeteries in Sydney and in the Guildford cemetery in Perth (Table 6).

Salmonella spp. bacteria were found in cemeteries in Brazil (Pacheco et al. 1991; Martins et al. 1991; Final 2007); however, they were not detected in groundwater in cemeteries in Poland, England, South Africa and Australia.

The research approaches used to evaluate the bacteriological contamination of the groundwater by cemeteries differ slightly in the regions studied. This fact hampers comparison of the results obtained. For example, in the World Health Organization report (Ücislık & Rushbrook 1988), attention has been drawn to the presence of B. cereus, faecal streptococci (S. faecalis), Micrococcaceae and Enterobacteriaceae in groundwater under cemeteries. In turn, the indicators of water contamination universally used in Brazil include the bacteria from the group of total coliforms (Citrobacter, Klebsiella and Enterobacter), faecal coliforms, thermotolerant coliforms (E. coli), Streptococcus (S. faecalis)
and Clostridium (C. perfringens) (CETESB 1996). Braz et al. (2000) have also noted Salmonella, lipolytic and proteolytic bacteria, whereas Matos & Pacheco (2000) identified heterotrophic bacteria. Few researchers have paid attention to viruses, e.g., coliphage 30, coliphage T134 and coliphage T4 (Final 2007). In Australia, the indicators of microbiological contamination include faecal coliforms, P. aeruginosa, as well as E. coli and faecal Streptococcus (Dent 2000b).

The role of environmental factors – summary

The review revealed the large influence of climatic conditions on the bacteriological contamination of the groundwater, at the regional scale. Most researchers express the opinion that warmer and moister climate is the principal factor in significant contamination of the environment – including the groundwater (Silva, J. A. F. 2000; Silva, L. M. 2000). They observed that during long-lasting periods of rainfall, microorganisms can be transported even over a distance exceeding 100 m. The Brazilian researchers are of the opinion that this negative impact could be contained through proper burial site management and the correct placement of cemeteries (Silva, J. A. F. 2000; Silva, L. M. 2000). Therefore, in many reviewed studies the role of other environmental factors was emphasized. These factors influence the groundwater pollution, especially at the local scale. Many researchers emphasized the role of geological settings and lithology of substrate, the relief conditions as well as the depth of the groundwater table and its fluctuation (Gray et al. 1974; Pacheco et al. 1991; Martins et al. 1991; Engelbrecht 1993; Rodrigues & Pacheco 2003; Almeida et al. 2006; Żychowski 2008). These factors were often responsible for spatial diversity of the groundwater contamination within a cemetery and its vicinity (Pacheco 1986; Antunes et al. 1998; Dent 1998; Morgan 2004). It is particularly significant for the cemeteries situated on slopes.

Geological settings and lithology of substrate affect infiltration rate, sorption capacity and groundwater circulation. In this way, these factors influence migration of the microorganisms – both in time and distance (Pacheco 1986; Silva 1994; Dent 2004). In this context, few studies revealed some kind of regularity. As the distance from the places of interment increases, the quantity of microorganisms rapidly decreases (Mello et al. 1995; Knight & Dent 1998; Dent & Knight 1998; Oliveira et al. 2002). This regularity was observed mainly in sandy clays and clayey grounds, and was explained by limited infiltration. The role of the substrate sorption capacity was emphasized by Matos (2001), Dent et al. (2004) and Josias & Harris (2004). The higher the sorption capacity (e.g., in clays) the more viruses were retained. The fine-grained substrate may also retain larger organisms such as bacteria during the filtration process. In this context, silty substrates more effectively retain bacteria contrary to coarse sand (Matos 2001).

Pathogens quickly migrate to the groundwater when the water table is shallow, e.g., in periods of intensive precipitation (Pedley & Guy 1996; Josias & Harris 2004). The pathogens die faster in the aeration zone than in the saturation zone and their transport in the saturation zone is slower than the groundwater flow (Gray et al. 1974). Many reviewed studies revealed some kind of regularity, namely, the more shallow the groundwater table the more bacteria occur in the water.

Many studies confirmed higher numbers of microorganisms in the vicinity of graves less than a year old (Pacheco 1986; Martins et al. 1991; Matos 2001; Migliorini 2002; Morgan 2004; Almeida et al. 2006) as well as near those which were placed close to the groundwater table (Dent & Knight 1998; Matos 2001; Costa et al. 2002; Almeida et al. 2006; Abrão 2007; Final 2007; Żychowski 2008).

According to Australian researchers, the groundwater contamination could also be predisposed by: (1) the lack of sewage systems at cemeteries; (2) errors made in grave construction; (3) faults in preparation and interment of corpses; (4) leaky tombs, cracks in graves; and, finally, (5) the lack of appropriate collection and utilization of solid waste in cemeteries (Silva et al. 2008). The researchers in South Africa see a dependence of the impact of cemeteries on groundwater contamination with one or more of the following factors: (1) the number of interments; (2) the physical, chemical and biological properties of natural habitats; (3) fluctuation in groundwater tables; (4) circulation of water in the substrate; and (5) the processes of binding between the decomposition products and the substrate, soil and organic matter (Wright 1999).

A number of cemeteries are parts of urban areas (Hirata & Suhogusoff 2004). In the context of studies presented in this review, evaluation of the cemetery impact on the
groundwater contamination must be well balanced. It should take into account the influence of other factors natural and anthropogenic – e.g., the lack of sewage systems or their leaking, conservation and cleanliness of wells (Mello et al. 1995; Braz et al. 2000; Espíndula 2004; Almeida et al. 2006; Sousa et al. 2008; Leite 2009).

**Recommendations**

The reviewed studies allow development of some recommendations intended to protect the health of employees of funeral homes and the residents living in the vicinity of cemeteries, as well as preserve the natural environment for future generations. Therefore, this review is summarized by the following list of recommendations:

1. Location of new cemeteries, and expansion and management of existing cemeteries should be preceded by obtaining appropriate environmental licence (e.g., Gambin et al. 2008). In this context the legal regulations are required. Older cemeteries should be successively changed and adapted to the new requirements.

2. Cemeteries should be located on gentle slopes. Higher slope gradients create favourable conditions for surface flow, flooding of graves, leaching and migration of decomposition products.

3. Cemeteries should be located on bedrocks where:
   (a) the clay mineral content ranges between 20 and 40%;
   (b) the bottom of the grave is at least 1.5 m above the maximum groundwater level. When the substrate has a permeability ranging from $10^{-5}$ to $10^{-7}$ cm·s$^{-1}$ (or higher), this distance should be higher.

4. Cemeteries should not be located in areas where:
   (a) the groundwater level is shallow;
   (b) seasonal or ephemeral floods occur;
   (c) the substrate is very permeable (e.g., sands and gravels, fractured rocks, karst structures);
   (d) the substrate has low permeability (e.g., clays and loams) and anaerobic conditions create favourable conditions for adipocere.

5. Cemeteries and the neighbouring areas should have stormwater drainage systems.

6. Cemeteries should be surrounded by buffer zones composed of trees with deep root systems.

7. The groundwater in cemeteries should be monitored both in terms of biological contamination and the depth of its table level.

8. People responsible for management processes in a cemetery should:
   (a) develop a model for storing special waste, i.e., human corpses;
   (b) establish recommendations concerning appropriate treatment of remains and leachates;
   (c) establish recommendations in order to prevent migration of decomposition products into the substrate;
   (d) establish recommendations for preparation of interments; those should focus on: construction of coffins, the manner of preparing corpses (including embalming), conservation of coffins, clothing items placed in coffins;
   (e) establish recommendations concerning maintenance of gravestones and their surrounding areas (including their conservation practices); these solutions should be authorised by the relevant environmental agencies.

9. People directly involved in the interment of victims of catastrophic events, namely soldiers, paramedics and other people exposed to infectious bacteria should be equipped properly.

10. Employees of funeral homes should use appropriate boots, gloves and face masks during work related to burials or exhumations. They should wash their hands and take a shower before leaving the cemetery.
