

# Hydrogeochemistry, water quality and health risk assessment of water resources contaminated by agricultural activities in Korkuteli (Antalya, Turkey) district center

Simge Varol and Mediha Şekerci

## ABSTRACT

Groundwater is a major water source for drinking, domestic and agricultural activities in the Korkuteli district. However, the intensive agricultural activities in the region negatively affect the groundwater quality. In this study, 30 water samples were collected from springs, wells, and tap waters in dry and wet seasons. Ca-Mg-HCO<sub>3</sub> and Mg-Ca-HCO<sub>3</sub> were dominant water types in the study area. According to the Gibbs diagrams, which were prepared to determine the mechanism controlling the groundwater geochemistry, samples from both seasons fell in the rock-dominance zone. The water quality index indicates the increase of ion concentrations due to the agricultural effect along with the rainwater in the region. Also, according to WHO standards, water samples are not appropriate to use as drinking water in terms of the heavy metal and fertilizers analysis results. In terms of the irrigation usage, most groundwater samples are suitable in dry and wet seasons. According to HCO<sub>3</sub> and SO<sub>4</sub> results, the mentioned samples can induce incrustation on metal surfaces and therefore are not recommended for industrial use. Groundwater chemistry in the study area is affected with water-rock interaction and dense agricultural activities. In conclusion, the study area is at high risk in terms of the health risk assessment.

## INTRODUCTION

Water is not only the essence of life, but also one of the most important factors determining the quality of human life. The quality of water is extremely important because it is essential for life. The fact that currently 75% of the earth is covered with water gives the idea that there is no water shortage in the world, but the potable water rate is only 0.74% of all waters worldwide (Akin & Akin 2017). In addition, emerging climate changes, developing technology and increasing population are the biggest problems in reaching healthy water today. These problems cause surface waters to gradually decrease and become unusable.

A result of this, groundwater is widely used. However, groundwater is not endless and not always suitable for the intended purpose. For this reason, it is very important to determine the amount of groundwater, the quality of the waters and their usage areas. In addition, knowledge of the geochemical evolution of groundwater characteristics is important for the sustainable development and effective management of water resources.

Pollution of groundwater is one of the most significant environmental problems in the world in recent years (Kumar *et al.* 2014). Groundwater quality depends on the

quality of the recharged water, rain and geochemical processes. The quality of groundwater reflects the combined effect of many processes along the groundwater flow path, at any point underground. Geochemical processes are responsible for the seasonal and spatial variation of groundwater chemistry. It is possible to divide the factors affecting these geochemical processes into geogenic and anthropogenic. Geogenic factors are related to geological, hydrological and hydrogeological conditions. Anthropogenic factors that change the chemistry and quality of groundwater are the result of domestic, irrigation and industrial uses. However, at the same time, degradation of the groundwater quality affects its use for drinking, agriculture and industrial activities. Today, approximately 80% of diseases all over the world and one third of deaths in developing countries are caused by polluted drinking water (WHO 2004). Therefore, the determination of the groundwater quality is important for the suitability of the water.

In this study, Korkuteli district in Antalya province, located in the southwest of Turkey, was chosen as a study area. In Korkuteli district, groundwater is the major source of water for human consumption and irrigation. Korkuteli district is an important region of Antalya, especially in terms of greenhousing and other agricultural activities related to livestock. These activities pollute the groundwater anthropogenically. Therefore, groundwater quality in this area is very important in terms of determining the suitability of water for drinking, domestic and agricultural purposes in the study area. In relation to this, the fact that the effect of agricultural activity on the water resources of the region has not been studied in detail before is a major deficiency for the study area. This study aims to resolve this deficiency and the results are important to determine the quality and usability with regard to sustainable management of water resources in the region.

## MATERIALS AND METHODS

### Study area

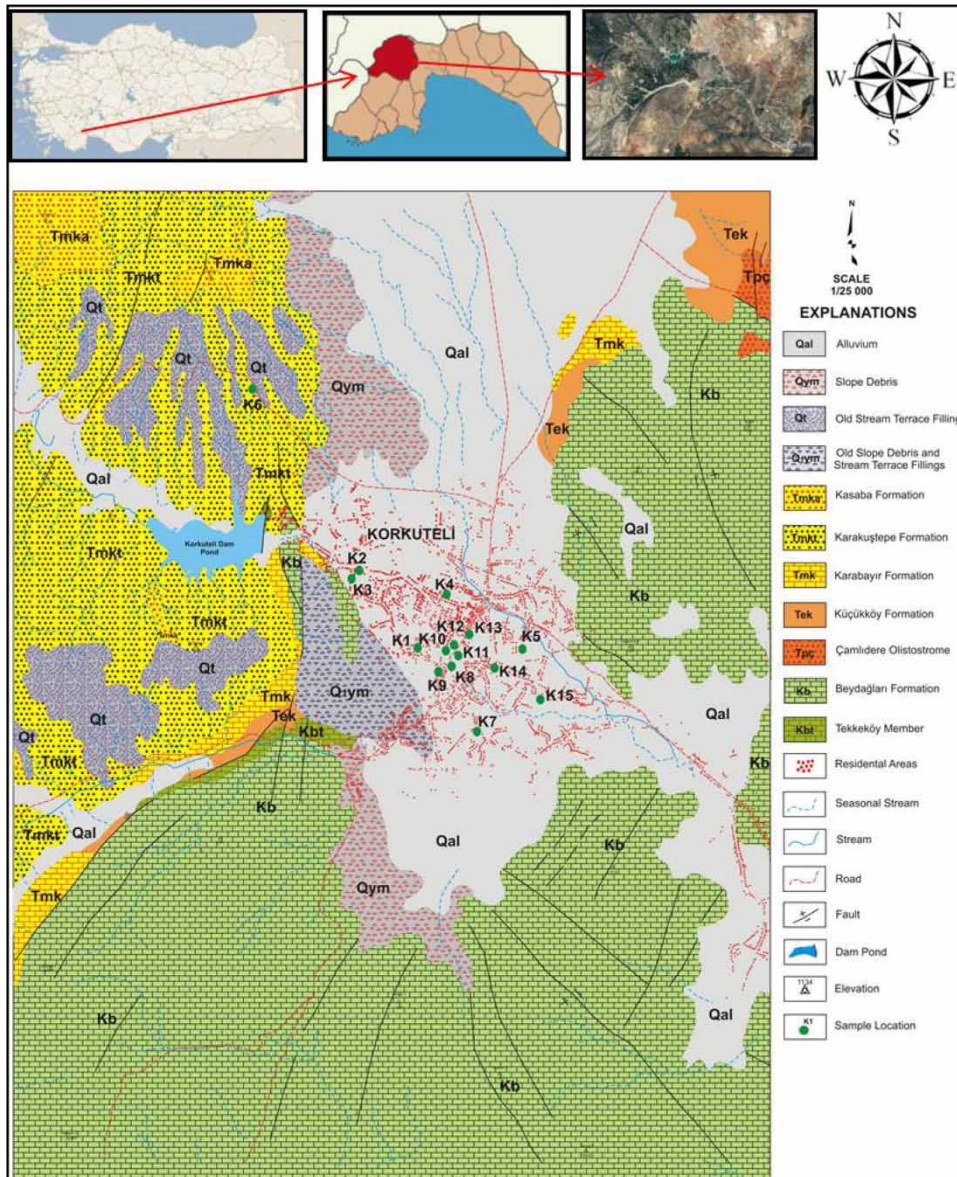

Korkuteli district center is located between latitude 37° 3' 51.9336" N and longitude 30° 11' 47.7132" E coordinates

(Figure 1). Korkuteli district center (area 121 km<sup>2</sup>) was selected as the study area due to the dense agricultural activity and settlement area. The altitude of the district center is 1,020 m. In general, the Mediterranean climate and the terrestrial climate prevail in the district. The mean rainfall for the study area was calculated as 316.39 mm (between 1969 and 2016) by the isohyet method (a line drawn on a map connecting points that receive equal amounts of rainfall) using the data from the meteorological stations in the study area and surrounds. In addition, the mean evapotranspiration was 324.84 mm. The drinking water of the district center is supplied from the springs and well waters in the study area. Also the irrigation waters are supplied from the well and surface flows. Korkuteli and Salamur streams are the most important surface flows in the study area (APESR 2012).

### Sampling and analysis

A total of 30 water samples from wells, springs and tap waters were analyzed in November 2016 (dry period) and May 2017 (wet period) for the determination of their major and minor chemical characteristics. The water samples were collected in two plastic bottles, pre-washed with 0.5% nitric acid (HNO<sub>3</sub>) and deionized water from each sampling point. During sampling, two bottles were filled with water from each spot, filtered, and a few drops of HNO<sub>3</sub> were added to one water sample that was used to detect major cations, while the second sample was not acidified and was used to detect major anions. All samples were transported and kept in the dark at 4 °C for analysis. The physical parameters, such as hydrogen ion concentration (pH), electrical conductivity (EC), total dissolved solids (TDS), oxidation–reduction potential (Eh) and discharge temperature (°C), were determined *in situ* using a YSI multi-parameter water quality sonde (YSI 6050).

The major chemical constituents (cations) were analyzed by ICP-MS (inductively coupled plasma-mass spectrometer) at the Bureau Veritas Commodities Canada Ltd (ACME Laboratory Vancouver, Canada, an ISO 9002 accredited company). Bicarbonate (HCO<sub>3</sub>), carbonate (CO<sub>3</sub>) concentrations were determined by the titrimetric method; chlorine (Cl), sulphate (SO<sub>4</sub>), nitrate

**Figure 1** | Location and geological maps of the study area.

(NO<sub>3</sub>), nitrite (NO<sub>2</sub>) and ammonium (NH<sub>4</sub>) were determined using ion chromatography in the Hacettepe University Water Chemistry Laboratory (Ankara, Turkey) (Table 1). The charge-balance error in the water samples was less than 5%, which is within the acceptable limits. All mathematical calculations were calculated using *Excel 2007* (Microsoft Office). Statistical analysis, such as the correlation matrix, was performed using the *SPSS* software version 15.

## Methods

### Water quality index (WQI)

The relative weight ( $W_i$ ) is computed from the following equation,

$$W_i = \frac{w_i}{\sum_{i=1}^n w_i} \quad (1)$$

**Table 1** | Analytical methods used in the study

| Type of samples             | Analysis parameters  | Method                | Name of laboratory  |
|-----------------------------|--|-----------------------|---|
| Water samples<br>(Total 30) | Discharge temperature (T/C), pH, TDS and electrical conductivity (EC)  | <i>In situ</i>        | <i>In situ</i>  |
|                             | Ag, Al, As, Au, B, Be, Bi, Br, Ca, Cd, Ce, Cl, Co, Cr, Cs, Cu, Dy, Er, Eu, Fe, Ga, Gd, Ge, Hf, Hg, Ho, In, Ir, K, La, Li, Lu, Mg, Mn, Mo, Na, Nb, Nd, Ni, Os, P, Pb, Pd, Pr, Pt, Rb, Re, Rh, Ru, S, Sb, Sc, Se, Si, Sm, Sn, Sr, Ta, Tb, Te, Th, Ti, Tl, Tm, U, V, W, Y, Yb, Zn, Zr | ICP mass spectrometry | ACME Laboratory (Vancouver, Canada, an ISO 9002 accredited company) |
|                             | SO <sub>4</sub> <sup>2-</sup>  | Ion chromatography    | Hacettepe University Water Chemistry Laboratory (Ankara, Turkey)    |
|                             | Cl <sup>-</sup>  | Titrimetric           | Hacettepe University Water Chemistry Laboratory (Ankara, Turkey)    |
|                             | NO <sub>3</sub> <sup>-</sup> , NO <sub>2</sub> , NH <sub>4</sub> <sup>+</sup>  | Ion chromatography    | Hacettepe University Water Chemistry Laboratory (Ankara, Turkey)    |
|                             | HCO <sub>3</sub> <sup>-</sup> , CO <sub>3</sub> <sup>2-</sup>  | Titrimetric           | Hacettepe University Water Chemistry Laboratory (Ankara, Turkey)    |

where  $W_i$  is the relative weight,  $w_i$  is the weight of each parameter, and  $n$  is the number of parameters.

In the next step a quality rating scale ( $qi$ ) for each parameter is assigned by dividing its concentration in each water sample by its respective standard according to the guidelines laid down in the World Health Organization (WHO 2011) and Turkish Standards Institution (TSI 266 2005), and the result is multiplied by 100 (Equation (2)):

$$qi = \left(\frac{Ci}{Si}\right) \times 100 \quad (2)$$

where  $qi$  is the quality rating,  $Ci$  is the concentration of each chemical parameter in each water sample (mg/L), and  $Si$  is the drinking water standard for each chemical parameter (mg/L) according to the guidelines of the WHO (2011) and TSI 266 (2005).

For computing WQI, the  $SI$  is first determined for each chemical parameter, which is then used to determine the WQI as per the following Equations (3) and (4),

$$Sli = Wi \times qi \quad (3)$$

$$WQI = \sum Sli \quad (4)$$

where  $Sli$  is the sub-index of  $i$ th parameter,  $qi$  is the rating based on concentration of  $i$ th parameter, and  $n$  is the number of parameters.

### Gibbs ratios

In addition, the Gibbs ratios (Gibbs 1970) were used to determine the mechanism controlling groundwater geochemistry. These ratios were calculated using the following formulas:

$$\text{Gibbs Ratio - I (for Anion)} = \frac{Cl^-}{(Cl^- + HCO_3^-)} \quad (5)$$

$$\text{Gibbs Ratio - II (for Cation)} = \frac{(Na^+ + K^+)}{(Na^+ + K^+ + Ca^{2+})} \quad (6)$$

### Health risk assessment

In this study, both the chronic and carcinogenic risk levels were also assessed. Generally, the hazard quotient (HQ **noncancer**) can be calculated by the following Equation (7) (USEPA 1998),

$$\text{HQ noncancer} = \frac{ADD}{RfD} \quad (7)$$

where the  $\text{NO}_3^-$ , arsenic (As) and chromium (Cr) toxicity reference doses (RfD) are 1.6, 0.0003 and 0.003 mg/kg/day, respectively (USEPA 2005). Non-cancer risk was represented in terms of an HQ **noncancer** for a single substance separately. If the exposure level of a substance exceeds the corresponding RfD, i.e., HQ **noncancer** exceeds 1, there may be concern for potential non-carcinogenic effects. The higher the mean value the greater the likelihood of an adverse non-carcinogenic health effect (USEPA 1998; Khan *et al.* 2008; Muhammad *et al.* 2010; Varol & Davraz 2016).

The cancer risk ( $R_{\text{cancer}}$ ) was calculated using Equation (8):

$$R_{\text{cancer}} = \text{ADD} \times \text{CSF} \quad (8)$$

where R is the excess probability of developing cancer over a life time as a result of exposure to a contaminant (or carcinogenic risk), ADD is the chronic daily intake (mg/kg/day), and CSF is the slope factor of the contaminant (mg/kg/day) (Equation (8)). According to the US EPA (2005) database the CSF of the contaminant for As is 1.5 mg/kg/day.

## RESULT AND DISCUSSION

### Geological and hydrogeological setting

The lithological units and interaction time of water with these units control the chemical composition of the groundwater. Firstly the lithological units in the study area have been investigated. All of the lithological units in the study area are autochthonous. These units are Beydağları autochthonous and quaternary alluvium (Qal), slope debris (Qym), old stream terrace fillings (Qt) and old alluvium-slope debris (Q1ym) (Şenel *et al.* 1989; Şenel 1997; Figure 1, Table 2). Beydağları autochthonous units are composed of Beydağları formation (Kb), Tekkeköy members (Kbt), Çamlıdere olistostrome (Tpç), Küçükköy formation (Tek), Karabayı formation (Tmk), Karakuştepe formation (Tmkt) and Kasaba formation (Tmka) (Şenel *et al.* 1989; Şenel 1997).

Secondly, lithological units in the study area were evaluated according to their hydrogeological properties. The general characteristics and hydrogeological properties of the

lithological units are given in detail in Table 2. Alluvium and quaternary units represent the most important granular aquifer in the study area (Aqf-1) and have an area of about 45 km<sup>2</sup>. Limestones can contain significant amounts of groundwater in cracks and melting spaces which allow water to move. For this reason the Beydağları formation, consisting of neritic limestones, and the Karabayı formation, consisting of algae limestones, are defined as 'karstic aquifer' (Aqf-2). The Karstic aquifer is the other important aquifer in the study area. The majority of water resources in the study area are discharged from the alluvium and limestones (Figure 1). The Kasaba formation, which consists of conglomerates and sandstones, is classified as 'aquitard' (Aqt). Çamlıdere olistostrome, Karakuştepe formation and Küçükköy formation in the study area are classified as 'aquifuge' (Aqj) due to their lithological characteristics (Table 2).

### Hydrogeochemistry

Groundwater chemistry is controlled by hydrogeochemical processes. There are many chemical processes during the movement of the groundwater from the recharge area to the discharging area. Some of these processes include precipitation, ion exchange, redox condition, leaching and dissolution. The chemical properties of the water determine the usage status for domestic, industrial or agricultural activities. In many developed and developing countries water pollution is one of the most significant factors for the spread of diseases and infant deaths (Kumar *et al.* 2016). The causes of water pollution can be classified as natural and anthropogenic sources. Accordingly, it is important to know the chemical properties and quality of water for the management and evaluation of groundwater (Kumar *et al.* 2016). For this reason, in this study we have attempted to determine the physicochemical properties, chemical properties and quality of groundwater in the study area.

### Seasonal evaluation of physical parameters

The pH of spring waters (according to the measurement method used for pH, the lower limit of quantitation is  $\pm 0.01$ ) varied between 8.71–9.36 and 8.88–9.60 for the dry and wet season, respectively. The pH values of the well waters were measured at 8.54–9.33 in the dry season and

**Table 2** | Lithostratigraphic relations of the geologic units and hydrogeological properties

| Age                              | Formation                             | Lithology   | Hydrogeological properties |
|----------------------------------|---------------------------------------|---|----------------------------|
| Quaternary                       | Alluvium (Qal)                        | Gravel sand and mudstone  | Aqf-1 (Granular aquifer)   |
| Quaternary                       | Slope debris (Qym)                    | Attached to the loose gravel, sand and mudstone   | Aqf-1 (Granular aquifer)   |
| Quaternary                       | Old stream terrace fillings (Qt)      | Round pebbles, medium-sized conglomerates   | Aqf-1 (Granular aquifer)   |
| Quaternary                       | Old alluvium and slope debris, (Q1ym) | Attached to small amount of gravel and sand attached  | Aqf-1 (Granular aquifer)   |
| Jurassic-Cretaceous              | Beydağları formation (Kb)             | Neritic limestones  | Aqf-2 (Karstic aquifer)    |
| Jurassic-Cretaceous              | Tekkeköy member (Kbt)                 | Locally cherty nodular and calcarenite intermediate level, locally abundant globotruncanic micrit | Aqj (Aquifuge)             |
| Lower Paleocene (Danian)         | Çamlidere olistostrome (Tpç)          | Micrit, clayey micrite, claystone, marl, calcarenite, sandstone and similar rocks                 | Aqj (Aquifuge)             |
| Upper Lutetian-Priabonian        | Küçükköy formation (Tek)              | Carbonate intermediate marl, claystone, limestone and clayey limestones                           | Aqj (Aquifuge)             |
| Akitanian-Lower Burdigalian      | Karabayır formation (Tmk)             | Algae limestones  | Aqf-2 (Karstic aquifer)    |
| Burdigalian                      | Karakuştepe formation (Tmkt)          | Sandstone, claystone, siltstone   | Aqj (Aquifuge)             |
| Upper Burdigalian-Lower Langiyen | Kasaba formation (Tmka)               | Conglomerates and sandstones  | Aqt (Aquitard)             |

8.89–9.30 in the wet season. Also, the pH of the tap waters varied for the dry and wet season between 8.76–8.93 and 8.85–8.92, respectively. The pH values of all water samples increased in the wet season (Table 3).

The EC values, EC, of spring waters (according to the measurement method used for EC, the lower limit of quantitation is 0.0001–0.01  $\mu\text{S}/\text{cm}$ .) were measured to be between 288.80–695.00  $\mu\text{S}/\text{cm}$  in the dry season and 279.80–708.00  $\mu\text{S}/\text{cm}$  in the wet season. The EC values of well waters also varied in the range of 317.10–794.00  $\mu\text{S}/\text{cm}$  in the dry season and 309.90–809.00  $\mu\text{S}/\text{cm}$  in the wet season. Also, the EC values of tap waters were measured in the range of 474.60–638.00  $\mu\text{S}/\text{cm}$  in the dry season and 424.00–744.00  $\mu\text{S}/\text{cm}$  in the wet season (Table 3). The high EC values in the wet season indicated the spatial variability of leaching and dilution with recharging rainfall. Also, the higher EC values in the wet season might be attributed to enhanced chemical weathering and lengthier residence time of groundwater in the aquifers (Oinam *et al.* 2011; Alam *et al.* 2016).

In addition, the temperature, T ( $^{\circ}\text{C}$ ), values of spring waters (according to the measurement method used for

T ( $^{\circ}\text{C}$ ), the lower limit of quantitation is 0.001  $^{\circ}\text{C}$ ) were measured in the range 12.10–15.50  $^{\circ}\text{C}$  in the dry season and 11.80–15.30  $^{\circ}\text{C}$  in the wet season. The T ( $^{\circ}\text{C}$ ) values of well waters also varied in the range 11.80–17.60  $^{\circ}\text{C}$  in the dry season and 14.70–17.80  $^{\circ}\text{C}$  in the wet season. Also, the T ( $^{\circ}\text{C}$ ) values of tap waters were measured in the range 13.10–17.10  $^{\circ}\text{C}$  in the dry season and 15.00–16.60  $^{\circ}\text{C}$  in the wet season (Table 3).

Oxidation–reduction potential, Eh, is a measurement that indicates the degree to which a substance is capable of oxidizing or reducing another substance (APHA 1998). In the present study, Eh values were measured to range from 319.50–400.80 mV in the dry season to 298.90–388.70 mV in the wet season (according to the measurement method used for Eh, the detection limit is 0.1 mV) (Table 3).

### Seasonal evaluation of major ions

The most common cations in the groundwater were calcium (Ca) and magnesium (Mg). Subsequently, sodium (Na) and potassium (K) ions were present in the

**Table 3** | Physicochemical characteristics of groundwater and tap water in the study area (dry and wet season)

| Parameters<br>(mg/l)              | LOQ* (mg/l)                             | Dry season       |                  |         |         | Wet season       |                  |        |         | Drinking water standards |               |                   |

\*LOQ, the lower limit of quantitation for each parameter.

composition of the water in lesser amounts (Tables 3 and 4). The sources of Ca and Mg in water were generally carbonate-rich rocks such as limestone and dolomitic limestone. An increase in Mg ion in the dry and wet seasons was observed at several locations (K1, K4, K5, K7, K11, K12, and K13). The major source of Mg in the

groundwater was from interaction of dolomitic limestone with water.

Bicarbonate (HCO<sub>3</sub>) was the main anionic constituent of the groundwater samples ranging from 225.70 to 506.30 mg/L in the dry season and from 236.65 to 517.80 mg/L in the wet season (Tables 3 and 4). HCO<sub>3</sub>,

**Table 4** | The major ion sequences of water samples

representing the major source of alkalinity, generally prevails due to the dissolution of CO<sub>2</sub> and carbonates, reaction of silicates with carbonic acid (Ranjan *et al.* 2013) and oxidation of organic matter (Jeong 2001). Sulphate (SO<sub>4</sub>) ion, which originates from the oxidation of sulphite, was the most abundant after bicarbonate (Ranjan *et al.* 2013). Another reason for the excessive amount of sulfate in the groundwater is the presence of anthropogenic inputs. SO<sub>4</sub> concentrations in the study area ranged between 21.07 and 132.73 mg/L in the dry season and between 30.09 and 155.80 mg/L in the wet season (Tables 3 and 4). This situation also indicates the entrance of anthropogenic sulphate related to fertilizers in the study area.

### Seasonal evaluation of fertilizers and heavy metals

In the study, NO<sub>2</sub>, NO<sub>3</sub>, NH<sub>4</sub> and heavy metal analyses (aluminum (Al), As, cadmium (Cd), copper (Cu), Cr, iron (Fe), manganese (Mn), nickel (Ni), lead (Pb), zinc (Zn)) were made to determine pollutant types and sources (Table 3). NO<sub>2</sub>, NO<sub>3</sub>, and NH<sub>4</sub> are pollutants which come mainly from agricultural and industrial effluents, contain a high concentration of nitrogen and are some of the largest contributors to

groundwater pollution in the world (Li *et al.* 2016). According to the results of analysis, NO<sub>2</sub> concentrations were determined as 0.00 mg/L in both periods. The detection limit for nitrite is ±0.001 mg/L. For this reason, the mean and standard deviation values for nitrite were not calculated (Table 3). NO<sub>3</sub> concentrations ranged from 2.19 to 21.34 mg/L in the dry season and ranged from 4.90 to 51.00 mg/L in the wet season. In addition, NH<sub>4</sub> concentrations were 0 mg/L in the dry season and 0–0.13 mg/L in the wet season (Table 3).

According to the heavy metal analysis results, Al concentrations were determined to be 0 mg/L in the dry season, and 0–0.05 mg/L in the wet season. As concentrations ranged from 0.08 to 0.17 mg/L in the dry season and ranged from 0.09 to 0.17 mg/L in the wet season. Cd concentrations were determined to be 0.05 mg/L in the dry season and 0 mg/L in the wet season. Cu concentration ranged from 0 to 0.04 mg/L in the dry season and from 0 to 0.87 mg/L in the wet season. Besides this, Cr concentrations were determined to be between 0.01 and 0.07 mg/L in the dry season and between 0.01 and 0.08 mg/L in the wet season. Fe concentration ranged from 0.01 to 0.11 mg/L in the dry season and ranged from 0.01 to 0.12 mg/L in the wet season. Mn concentration was determined as 0 mg/L

in both seasons. Ni concentrations were determined to be 0 mg/L in the dry season, and between 0–0.09 mg/L in the wet season. Pb concentrations were determined to be 0 mg/L in the dry season, and 0–0.01 mg/L in the wet season. Finally, Zn concentration ranged from 0 to 0.17 mg/L in the dry season and 0 mg/L in the wet season (Table 3). Accordingly, seasonal variation in NO<sub>2</sub>, NO<sub>3</sub>, NH<sub>4</sub> and heavy metals concentrations is thought to be related to infiltration of rainwater and agricultural activities.

## STATISTICAL ANALYSIS

### Correlation matrix

Correlation analysis was applied to determine the relationship between physicochemical properties of water samples. It is possible to obtain information about the mineral and chemical processes, and the chemical constituents of water with this relationship were determined by correlation analysis (Varol & Davraz 2015).

In this study, the Kolmogorov–Smirnov (K-S) test was initially used to determine the compatibility of the data to normal distribution (Varol & Şen 2009). According to the K-S test, all the variables were normally distributed with 94% confidence. For this reason, to evaluate the potential relationship between various physicochemical parameters and trace elements, Pearson correlation analysis (PCA) was carried out.

In correlation analysis, if the correlation coefficient is close to 1 or -1, it means a good positive relationship between the two variables. The near zero values are significant if  $p < 0.05$ , but there is no relationship between them. Thus, while it is assumed that there is strong correlation between the parameters with  $r > 0.7$ , it is said that the  $r$  value is moderately correlated between 0.5 and 0.7 (Manish *et al.* 2006).

All the processes were performed using SPSS software version 15.0 for Windows. In addition, the Pearson correlation matrix was applied separately for the dry and wet seasons in order to study the changes in the relations between the parameters. The correlation matrix of the parameters is given in Table 5 (dry season), and Table 6 (wet season). The analysis results of CO<sub>3</sub>, NO<sub>2</sub>, NH<sub>4</sub>, Cd, Mn, Ni and Pb in the dry season and CO<sub>3</sub>, NO<sub>2</sub>, Cd, Mn, Ni in

the wet season were 0.00 mg/l, and owing to this results were not evaluated in the correlation matrix.

According to the physicochemical PCA results, EC showed positive strong correlation with TDS, Mg, Na, HCO<sub>3</sub>, Cl, SO<sub>4</sub>, NO<sub>3</sub>, and Cr in dry and wet seasons. Also EC showed negative strong correlation with pH in the dry season. T (°C) showed negative moderate correlation with pH in the wet season. pH showed negative strong correlation with TDS, Ca, K, HCO<sub>3</sub>, NO<sub>3</sub> and showed negative moderate correlation with Mg, Cl and Cr ions in the dry season. In the wet season, pH showed negative moderate correlation with only Mg ion. Eh showed positive moderate correlation with As in the wet season only. TDS showed positive strong correlation with Mg, Na, HCO<sub>3</sub>, Cl, SO<sub>4</sub>, and NO<sub>3</sub>, Cr ions in the dry and wet seasons (Tables 5 and 6).

Ca showed positive moderate correlation with K, HCO<sub>3</sub> and NO<sub>3</sub> in the dry season and also showed positive moderate correlation with K. Mg showed positive strong correlation with Na, HCO<sub>3</sub>, Cl, SO<sub>4</sub>, NO<sub>3</sub>, Cr in the dry season. In the wet season it showed positive strong correlation with Na, HCO<sub>3</sub>, Cl, NO<sub>3</sub> and Cr, and showed positive moderate correlation with SO<sub>4</sub> the Na showed positive strong correlation with HCO<sub>3</sub>, Cl, SO<sub>4</sub> and Cr in the dry and wet seasons. It also showed positive moderate correlation with NO<sub>3</sub> and Cu in the dry season and showed positive moderate correlation with NO<sub>3</sub> and Cl. While K showed a positive moderate correlation with Al in the dry season and negative correlation with Al in the wet season (Tables 5 and 6).

In addition, according to the physicochemical PCA results, HCO<sub>3</sub> showed positive strong correlation with Cl, SO<sub>4</sub>, NO<sub>3</sub>, Cr in the dry and wet seasons. Cl showed positive strong correlation with SO<sub>4</sub>, NO<sub>3</sub>, and Cr in the dry season, and showed positive strong correlation with NO<sub>3</sub> and Cr, and positive moderate correlation with SO<sub>4</sub> in the wet season. SO<sub>4</sub> showed positive strong correlation with Cr in the dry and wet seasons and also showed positive moderate correlation with NO<sub>3</sub> and Cr in the dry season (Tables 5 and 6).

According to the PCA results of the heavy metal and pollution parameters, NO<sub>3</sub> showed positive moderate correlation with Cr in the dry and wet seasons. While Al showed positive moderate correlation with Fe in the dry season, it showed positive strong correlation with Fe in the wet season. Cu showed positive moderate correlation with Ni and Pb ions. Ni showed positive moderate correlation with

**Table 5** | Correlation matrix of dry season parameters waters in the study area

Pb ion (Tables 5 and 6). Statistical analysis results indicated that water resources were affected from rock-water interaction, climatic conditions, ion exchange processes and excess application of fertilizer in the study area.

### Hydrogeochemical facies

Hydrogeochemical facies are a useful tool for determining the chemical history and origins of groundwater. They are used to show similarities and differences in the chemistry of groundwater samples based on dominant cations and anions (Piper 1944, 1953). The hydrogeochemical evolution of groundwater in the study area was prepared separately for both dry and rainy periods and was evaluated using a Piper diagram using the concentrations of major cations (Ca, Mg, Na and K) and anions (HCO<sub>3</sub>, SO<sub>4</sub>, and Cl) in meq/l.

According to the Piper diagrams, in the study area Ca-Mg-HCO<sub>3</sub> and Mg-Ca-HCO<sub>3</sub> as the dominant water types were observed in both the dry and wet seasons (Figure 2). Ca-Mg-HCO<sub>3</sub> and Mg-Ca-HCO<sub>3</sub> facies represented 53.33% and 46.66% of the total water samples, respectively (Table 4; Figure 2). These water types originated from the dissolution of limestone and dolomitic limestone in the aquifer material.

### Mechanism controlling the groundwater geochemistry

Some diagrams have been proposed by Gibbs (1970) to determine groundwater chemistry, rock-water interaction in aquifers, and sedimentation mechanism in groundwater. There are two types of diagrams. The parameters used in these diagrams are dominant anions (Gibbs Ratio I) and cations (Gibbs Ratio II) and TDS values. These diagrams are extensively used to determine the chemical composition of the water in relation to processes such as precipitation, rock and evaporation dominance.

In this study, Gibbs Ratio I values varied from 0.01 to 0.04 with an average value of 0.02, and Gibbs Ratio II values varied from 0.08 to 0.52 with an average value of 0.24 in the dry season. Gibbs Ratio I values varied from 0.01 to 0.05 with an average value of 0.02, and Gibbs Ratio II values varied from 0.06 to 0.53 with an average value of 0.25 in the wet season. According to the Gibbs diagrams, water samples from dry and wet seasons fall in the rock dominance zone (Figure 3). The diagram indicates that chemical weathering

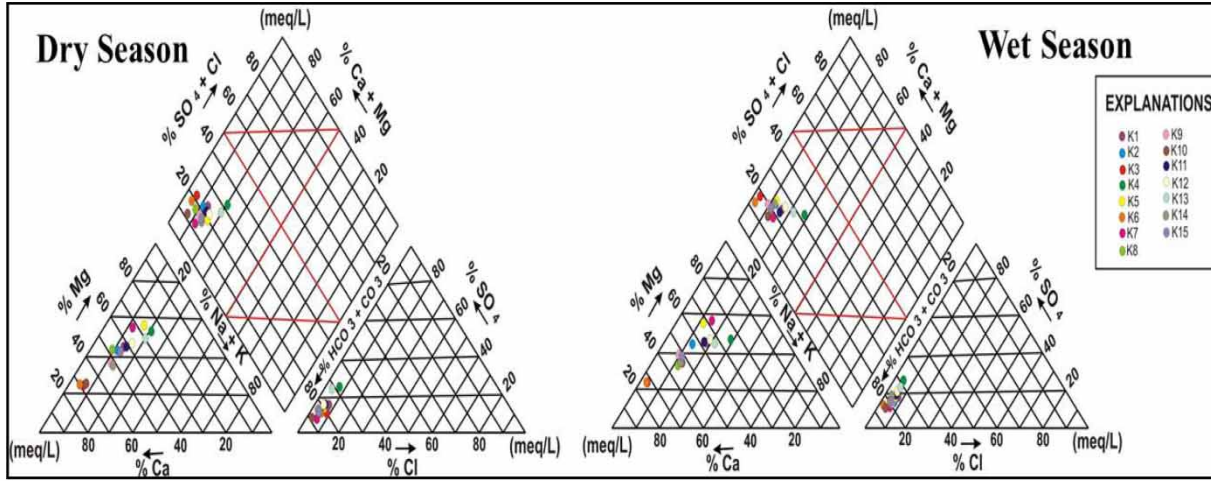

Figure 2 | Piper diagrams in dry and wet season (Piper 1944).

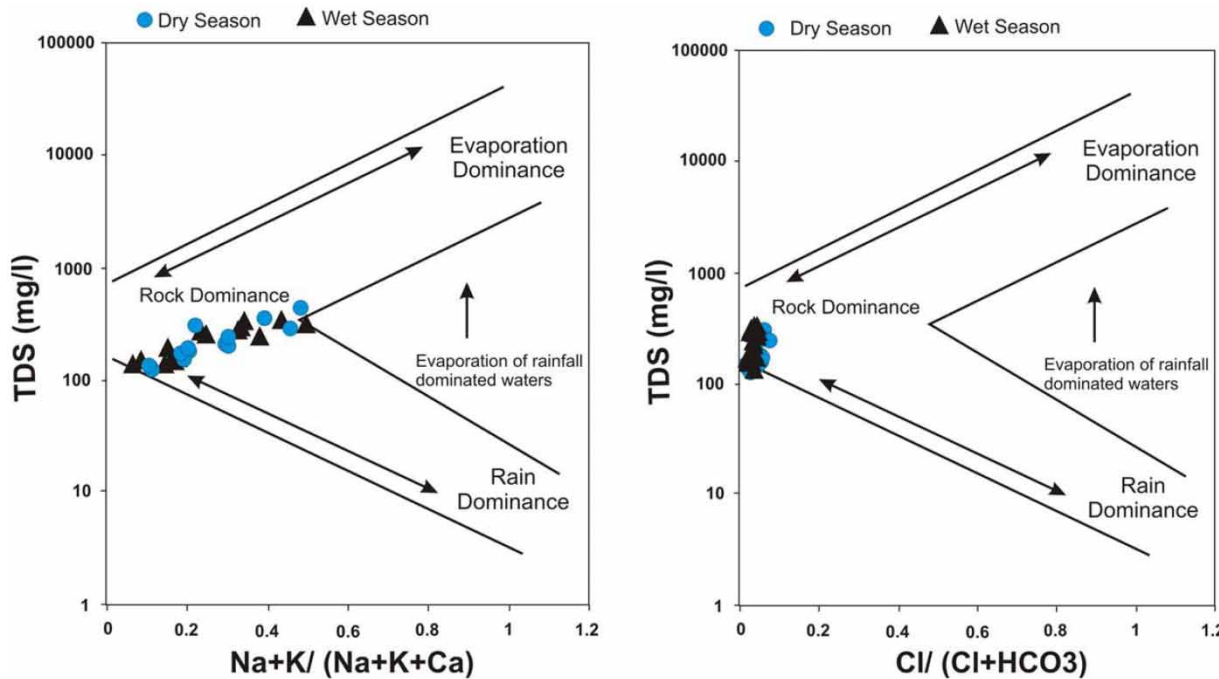

Figure 3 | Gibbs diagrams (Gibbs 1970) illustrating the mechanisms controlling the chemistry of groundwater samples.

of the rock-forming minerals is the main process through which ions are contributed to the groundwater.

### EVALUATION OF WATER QUALITY

In this section of the study, the water quality assessments were carried out to identify its suitability for drinking, irrigation, and industrial purposes.

### Evaluation of water quality as drinking water

#### Water quality index (WQI) evaluations

Water quality index (WQI) is defined as a method to determine the influence of each water quality parameter on the overall quality of water for human consumption (Varol & Davraz 2015). WQI is an important parameter for determining groundwater quality and its suitability for drinking

water. The WQI index is a measure of the composition of water in light of certain defined objectives. In general, the purpose of the index is to compare each of the main parameters of drinking water with the World Health Organization (WHO) and national standards (Yidana *et al.* 2010). In this study, WQI was computed in three steps. The analysis results were evaluated and compared with WHO (2011) and TSI 266 (2005) (Table 7).

Each of the 21 parameters (pH, TDS, Ca, Mg, Na, K, HCO<sub>3</sub>, Cl, SO<sub>4</sub>, NO<sub>2</sub>, NO<sub>3</sub>, NH<sub>4</sub>, As, Cr,) has been assigned a weight (wi) according to its relative importance for drinking water quality (Table 7). Greater weight is assigned to parameters which have critical health effects and whose presence above certain critical concentration limits could limit the usability of the resource for domestic purposes (Yidana *et al.* 2010). Therefore in this study, the maximum weight of 5 has been assigned to parameters including TDS, Cl, SO<sub>4</sub>, NO<sub>3</sub>, NO<sub>2</sub>, NH<sub>4</sub>, As and Cr due to their major importance for water quality assessment (Srinivasamoorthy *et al.* 2008). The minimum weight (1) has been assigned to the parameter HCO<sub>3</sub> due to its having the least importance for water

quality assessment. Other parameters, including pH, Ca, Mg, Na, and K, were assigned to weights between 1 and 5 depending on their importance in water quality determination.

Finally, the WQI values obtained from the calculations were evaluated together with the water quality types in Table 8. In addition, the WQI values for each sample and their types are shown in Table 9. According to Table 9, the calculated WQI values ranged from 113.15 to 177.67 and from 103.84 to 204.00 for dry season and wet seasons, respectively. In addition, during the dry season, 100% of groundwater samples represent 'Poor water'; during the wet season 93.33% of groundwater samples represent 'Poor water' and 6.66% indicate 'Very Poor water'. This indicates that the quality of wet season samples is very low. So, the increase of ion concentrations is related to infiltration of rainwater in the farmland.

#### Potability of water in terms of fertilizers and heavy metal concentrations

In many parts of the world, groundwater is exposed to pollution from fertilizers and pesticides due to human activities, mostly involving intensive agriculture and urbanization. Fertilizer usage varies according to soil structure, climate and plant species and nowadays, the most widely used fertilizers are nitrogen and its derivatives urea, phosphate and potassium fertilizers. One of the most common ways in which nitrogen and its derivatives pass into groundwater is leaching from agricultural lands. Accordingly, the nitrate level in the groundwater is greatly affected by fertilizer quantity and types (Rahmati *et al.* 2015). Chemical or artificial fertilizers contain heavy metals and metalloids at lower amounts compared with nitrogen and its derivatives. The continuous application

**Table 7** | Relative weight of physicochemical parameters in study area

| Chemical parameters          | WHO (2011) standards | Turkish Drinking Water Standard (TS 266) (2005) | Weight (wi) | Relative weight (Wi) |

of these fertilizers over the last fifty years may have contributed to increasing heavy metals and metalloids in soil and groundwater (Jayasumana *et al.* 2015).

In addition, chemicals associated with the use of excessive fertilizers and pesticides may cause negative effects on human health. Notably, excess nitrate in the drinking water can cause health risks such as methemoglobin, which depletes blood oxygen levels in infants, causes gastric problems in adults, decreased functioning of the thyroid gland, and cancer due to formation of nitrosamines, as well as multiple sclerosis (Zhaia *et al.* 2017). Other agrochemicals, such as arsenic (As), cadmium (Cd), chromium (Cr), copper (Cu), nickel (Ni) and lead (Pb), have toxic properties and pollute groundwater. Phosphorus-containing artificial fertilizers are the main source of agricultural As pollution in groundwater (Sönmez *et al.* 2008). Triple Super Phosphate (TSP) type phosphate fertilizers are one of the main sources of As. The amount of As in the TSP is 15 times greater than the insecticide *Dimethoate*, which has contained the highest level of As among insecticides. Arsenic in soil can contaminate drinking water and food crops including vegetables, fruits and field crops (Jayasumana *et al.* 2015). Groundwaters containing As considerably affect human

health and cause fatal consequences due to their carcinogenic effects. Epidemiologic studies have shown that As exposure is related to skin, liver, bladder, and other cancers (Lin *et al.* 2016).

The study area is an important region of intensive agricultural activity, particularly when it comes to greenhouse (Figure 4; ADPFAL 2011; APESR 2012). Agricultural products and cultivated areas in the region are given in Table 10 (ADPFAL 2016). The use of artificial fertilizers is very high in the study area. The fertilizer types and consumption quantities in the study area are given in Table 11 (ADPFAL 2016). According to Table 11, nitrogen and its derivatives urea, phosphate and potassium are the main groups of chemical fertilizers used in Korkuteli district.

WHO has specified the maximum safe nitrite, nitrate and ammonium concentration in drinking water to be 0.2, 50 and 1.5 mg/L, respectively (WHO 2011). Nitrate

concentrations exceeding the 50 mg/l limit value in drinking water can endanger human health, especially in infants (Vidyalakshmi *et al.* 2013). According to the analysis results, nitrate concentrations in the study area exceed the limit value only in the wet season (K2, K5 and K7). In addition, a nitrate level of 3 mg/L or greater indicates contamination. Water with a nitrate concentration of greater than 10 mg/L should not be used to prepare infant formula or other foods or be given to a child younger than 1 year to drink (Greer & Shannon 2005; PWP 2009). As water in the study area is used by people of all ages living in the region, this underlines the importance of this study. The analysis results showed that all waters in the study area both in dry and wet seasons were contaminated and these waters are not suitable for drinking owing to their nitrate concentrations (Table 3).

In addition, arsenic concentrations in all samples exceeded the threshold value determined by WHO (2011) in both periods. Cr concentrations exceeded the limit values at K1, K4 and K5 samples in the dry season and exceeded the limit values at K1, K2, K4, K5, K7, K11 and K12 samples in the wet season. In addition, Ni (K7 and K12) and Pb acceptable concentrations (K1, K7 and K12) were determined to be exceeded only during the wet season. Accordingly, it is not appropriate to use as

drinking water according to the heavy metal analysis results (Table 3).

### Evaluation of water quality as irrigation use

The sodium adsorption ratio (SAR), permeability index (PI), sodium percentage (Na %), magnesium hazard (MH), and residual sodium carbonate (RSC) indices were used to determine the suitability of groundwater for agricultural irrigation and the results are indicated in Table 12.

#### Sodium adsorption ratio

The calculated values of SAR ranged from 0.76 to 8.24, and 86.67% of the samples were considered 'no problem' for irrigation, but 13.33% of samples were considered as an 'increasing problem' for irrigation in the dry season. Apart from this, all samples fall into the 'no problem' category in the wet season (Table 12).

In addition, the relationship between SAR and EC values was prepared using a US salinity diagram for both seasons and the suitability of the waters for irrigation was evaluated. According to the diagram, 86.67% of the samples fall in the field of C<sub>2</sub>-S<sub>1</sub>, indicating

**Table 12** | Irrigational quality parameters results in groundwater samples in the study area

| Parameters   | Range     | Groundwater class (irrigation uses) | Samples (n = 15) in dry season |        | Samples (n = 15) in wet season |        |

|  | >2.50     | Unsuitable                          | –                              | –      | –                              | –      |

medium salinity and low alkalinity content. These waters can be suitable for irrigation. 6.66% of the samples fall in the field of  $C_2-S_2$  indicating medium salinity and medium alkalinity content, and 6.66% of the samples fall in the field of  $C_3-S_2$  category in the dry season, indicating high salinity and medium alkalinity content (Figure 5). The use of waters in  $C_2-S_2$  and  $C_3-S_2$  categories is limited to irrigation water. In the wet season, 73.33% of the samples fall in the category of  $C_2-S_1$  and 26.66% of the samples fall in the  $C_3-S_1$  category, indicating that these water samples are found to have high salinity and low sodium content, which can be used for irrigation in all soil types with low risk of sodium in the wet season (Figure 5).

### Permeability index

The PI values were between 37.21 and 50.63 in the dry season, and between 34.99 and 53.54 in the wet season. All samples fall into the 'Suitable' category for irrigation in dry and wet seasons (Table 12).

### Sodium percentage

In all natural waters, sodium percentage (%Na) content is one of the most important parameters to assess their suitability for agricultural purposes. This is because sodium increases the hardness of the soil, and decreases its permeability (Varol & Davraz 2015). This soil type prevents plant growth. Sodium percentage values of groundwater samples were calculated for the dry and wet seasons (Table 12). Sodium percentage of these samples was plotted against EC in a Wilcox diagram (Figure 6) and given in Table 12. According to the Wilcox diagram, 86% of all samples were in the 'Excellent to good' irrigation water class and 13% (K4, K13) were in the 'Good to permissible' irrigation water class in the dry and wet seasons.

### Magnesium hazard

Paliwal (1972) introduced a ratio MH for assessing the suitability of irrigation water quality. Generally, Ca and Mg maintain a state of equilibrium in water. Magnesium

Figure 5 | Salinity (EC) and sodium hazard (SAR) of irrigation water in US salinity diagram (dry and wet season).

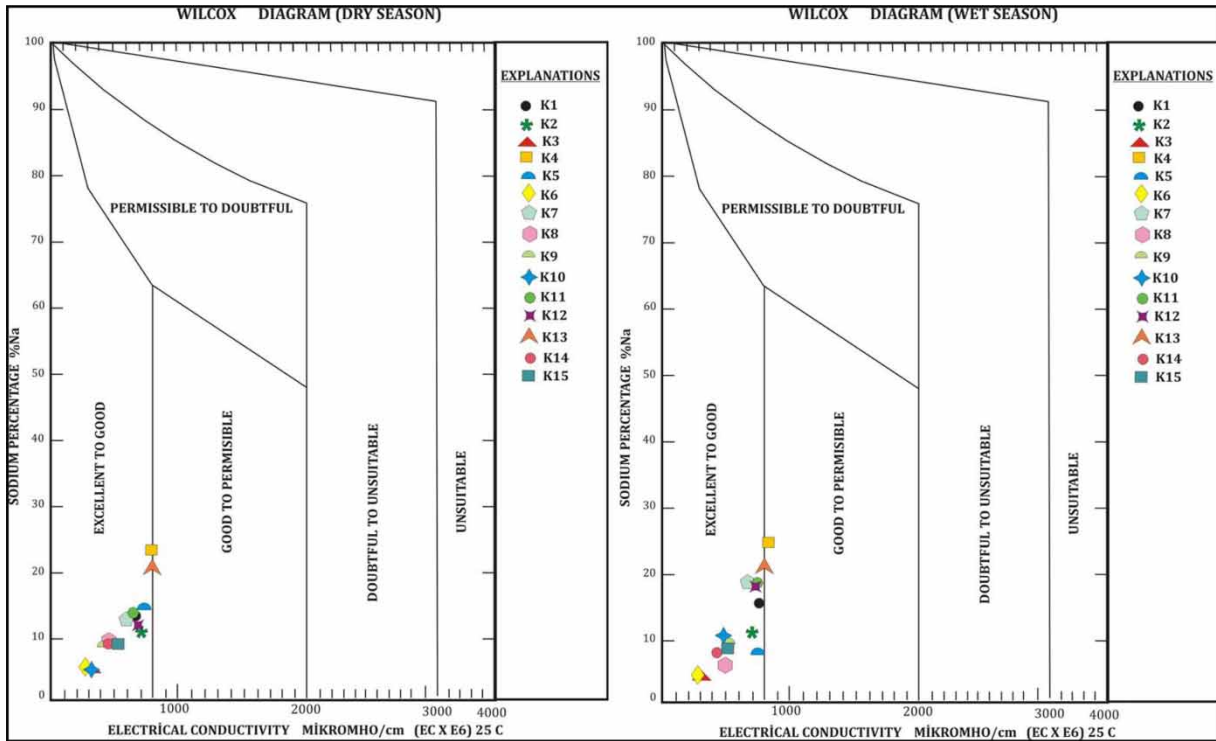

Figure 6 | According to the Wilcox (1955) diagram, irrigational suitability of groundwater in the dry and wet season.

damages the soil structure when water contains more Na and is highly saline. Generally, a high concentration of Mg is caused by the exchange of Na in irrigated soils. In equilibrium, the high Mg concentration can affect soil quality by changing its alkalinity. Thus, this situation affects crop yields (Varol & Davraz 2015). The MH values in the study area ranged from 41.51 to 68.04 and 53.33% of the samples were considered suitable for irrigation, the remainder of samples being considered unsuitable for irrigation owing to their adverse effect on crop yields in the dry and wet seasons (Table 12).

### Residual sodium carbonate

RSC is an important parameter for the suitability of irrigation water (Siddiqui *et al.* 2005; Varol & Davraz 2015). Excessive magnesium and calcium ions tend to precipitate as carbonate. The sodium concentration is increased and fixed to the soil and thus the soil permeability is reduced. The high RSC value in water causes an increase in the adsorption of sodium in the soil (Eaton 1950; Selvakumar *et al.* 2017). Lloyd & Heathcote (1985) have classified

irrigation water based on RSC as suitable (<1.25), marginal (1.25–2.5) and unsuitable (>2.5). According to RSC values, 100% of groundwater samples were suitable for irrigation in dry and wet seasons (Table 12).

### Evaluation of water quality for industry

Quality classifications for industrial water usage lie within a wide range and nearly every industrial unit has its own standards. Industries often have problems with the chemical reactions associated with poor water quality, such as incrustation and corrosion. Incrustation involves the deposition of undesirable  $\text{CaCO}_3$  on metal surfaces, whereas corrosion is a chemical process which causes the metals to wear out. For this reason, industrial use of water in the study area has also been examined in this study. The following water quality criteria were adopted when classifications were made (Johnson 1983; Subba Rao *et al.* 2012; Varol & Davraz 2015): (a) if water contains 400 mg/L of excess  $\text{HCO}_3^-$  or 100 mg/L of excess  $\text{SO}_4^{2-}$ , it may cause incrustation; (b) if water contains  $\text{pH} < 7$ , TDS more than

1,000 mg/L or Cl more than 500 mg/L, this water may cause corrosion.

In the present study, about 53.33% of the  $\text{HCO}_3$  concentrations of the samples (K1, K2, K4, K5, K7, K11, K12 and K13) exceeded the limit of 400 mg/L in dry and wet seasons. Also, in 13.33% of the samples (K4 and K13), the  $\text{SO}_4$  concentrations were more than 100 mg/L in dry and wet seasons. According to these results, the mentioned samples can induce incrustation on metal surfaces and are therefore not recommended for industrial use.

If the groundwater pH > 7, TDS is less than 1,000 mg/L and Cl is less than 500 mg/L, there is no corrosion effect. Therefore, there is no corrosion effect for any waters in the study areas.

### Health risk assessment

Risk assessment is an effort to identify and measure the effects of various pollutants on human health. It also includes evaluating toxicity data for human exposure to chemicals and estimating the potential exposure levels. There are three main routes to of exposure: ingestion, inhalation, and dermal absorption. Only the ingestion path was taken into account in this study due to its being the most common form of exposure to trace elements (Varol & Davraz 2016).

Generally, local people in the study area use both groundwater and tap water for drinking and domestic purposes. Therefore the water resources in this study, with regard to WHO (2011) and TSI 266 (2005) standards, exceed the safe limits of concentration for  $\text{NO}_3$ , As and Cr and could be the origin of problematic health effects (Tables 13 and 14). We evaluated the origin of these problems and their effects on health. The  $\text{NO}_3$ , As and Cr concentrations in drinking water have been used to calculate potential health risk assessments: chronic and carcinogenic effects such as average daily dose (ADD), HQ **noncancer** and carcinogenic risk (R cancer). The calculated health risk for residents is presented in Tables 13 and 14.

According to Tables 13 and 14, the values of ADD were between 0.16–1.07 (mg/kg) in the dry season and 0.21–1.49 (mg/kg) in the wet season for  $\text{NO}_3$ . The values of ADD were 0.00 (mg/kg) in the dry season and 0.09 and 0.17 mg/kg in the wet season for As. The values of ADD

were 0.00 (mg/kg) in dry season and wet season the wet season for Cr. The values of  $\text{HQ}_{\text{noncancer}}$  were 0.10–0.67 in the dry season and 0.13–0.93 in the wet season for  $\text{NO}_3$ . For As, the values of  $\text{HQ}_{\text{noncancer}}$  were between 7.62–16.19 in the dry season and 8.72–16.44 in the wet season. For Cr, the values of  $\text{HQ}_{\text{noncancer}}$  were 0.10–0.67 in the dry season and 0.11–0.75 in the wet season. Also, values of  $\text{R}_{\text{cancer}}$ , were 0.00–0.01 in the dry season and 0.13–0.25 in the wet season for As. Carcinogenic risk is the likelihood of developing any type of cancer against the risk of exposure to a substance that has a life-long toxic effect on a person. Acceptable or tolerable risk, as determined by the regulators of the subject, is in the range of  $10^{-6}$  to  $10^{-4}$  (USEPA 2000; WHO 2004; Muhammad *et al.* 2010).

According to Tables 13 and 14, the possibility of developing cancer is 1–2 patients out of every 10 healthy people in dry and wet seasons. Excessive consumption of water with a high concentration of As in the study area carries a high risk of cancer. In addition, there is a high risk of noncarcinogenic effects in terms of As. Furthermore, according to Turkish drinking water standards, concentrations of heavy metals (As and Cr) in water were evaluated in dry and wet seasons, and they also exceeded the limit values (Tables 13 and 14). This also supports the results of the health risk assessment. For this reason, it is an urgent requirement to develop more efficient As removal methods in this emerging situation. These results show that the study area is at high risk in terms of health. This is an alarming situation and there is a need to develop more effective arsenic removal methods and urgent remediation to protect the health of at-risk people in the study area.

### CONCLUSIONS

Groundwater quality and its suitability for different uses such as drinking, agriculture and industry in Korkuteli district were evaluated because groundwater is a major resource for domestic, agricultural, and industrial activities in the study area. In this study, a total of 30 water samples taken from wells, springs, and tap waters were analyzed in dry and wet seasons. The hydrogeochemical and water quality studies conducted in the groundwater of the Korkuteli district provides the following conclusions.

**Table 13** | Calculated carcinogenic and noncarcinogenic risk of drinking water (dry season)

| Substance       | Water sample no. | C (mg/l) | IR (l/day) | ED (years) | EF days/years | BW (kg) | AT (days) | ADD (mg/kg) | RfD (mg/kg/d)      | *CSF (mg/kg/d) <sup>-1</sup> | R cancer | HQ noncancer | (TSI 266) (2005) (mg/l) | WHO (2011) standards (mg/l) |

\*Data from USEPA (2005).

The seasonal variation of physical, major ion and heavy metal and pollutant concentrations of the water resources in the study area were evaluated. As a result, changes in the

physical and major ion concentrations of the water are associated with rock–water interactions. However, changes in the concentrations of heavy metals and nitrogen

**Table 14** | Calculated carcinogenic and noncarcinogenic risk of drinking water (wet season)

\*Data from USEPA (2005).

derivatives in the water are also related to anthropogenic inputs. In the wet season, infiltration of rain water changes the concentration values.

Statistical analyses were carried out to determine the hydrochemical properties of groundwater and tap water in the study area, and their relationships with each other.

The correlation analysis is a bivariate method that is applied to describe the degree of relationship between two hydrochemical parameters in dry and wet seasons. The parameters used for correlation analysis were T (°C), pH, Eh, EC, TDS, Ca, Mg, Na, K, HCO<sub>3</sub>, CO<sub>3</sub>, Cl, SO<sub>4</sub>, NO<sub>3</sub>, NO<sub>2</sub>, NH<sub>4</sub>, Al, As, Cu, Cr, Fe and Zn values of water. There was a moderate to strong correlation between some of the correlation groups in the study area ( $r > 0.7$ ). The reason for this is considered to be mainly the dissolution/precipitation reactions, concentration effects and anthropogenic inputs, in relation to the simultaneous increase/decrease in cations.

Ca-Mg-HCO<sub>3</sub> and Mg-Ca-HCO<sub>3</sub> were the dominant water types observed in dry and wet seasons, due to water-rock interaction in the study area. According to the Gibbs diagrams, samples from both seasons fell in the rock-dominance zone, suggesting precipitation induced chemical weathering along with dissolution of rock forming minerals.

The WQI was applied to determine the drinking water quality of the water samples in the study area. According to the WQI, in the dry season, 100% of groundwater samples represent 'Poor water' and during the wet season 93.33% of groundwater samples represent 'Poor water' and 6.66% indicate 'Very Poor water'. This indicates that the quality of wet season samples is very bad. The increase in ion concentrations is related to the infiltration of rain water in the farmland. In addition, nitrogen derivatives and heavy metal concentrations of water samples were compared and assessed with the limit values determined by the World Health Organization (WHO 2011) for the usability of drinking water. Accordingly, it is not appropriate to use as drinking water in terms of the heavy metal and nitrogen derivatives analysis results.

In addition, use as irrigation water in the study area was evaluated by SAR, PI, Na%, MH, RSC, USSS classification and Wilcox diagram. A large majority of water samples were suitable for irrigation purposes according to RSC, SAR, PI and Na%. According to the MH values, 53.33% of the samples were considered suitable for irrigation; meanwhile, 46.66% of samples were considered unsuitable for irrigation indicating their adverse effect on crop yields in the dry and wet seasons.

The groundwater quality was evaluated in terms of industrial usage. Because some water types can cause

incrustation and corrosion on metal surfaces, they cannot be used. Therefore, HCO<sub>3</sub>, SO<sub>4</sub>, pH, TDS and Cl concentrations of waters were evaluated. According to HCO<sub>3</sub> and SO<sub>4</sub> results, the studied samples can induce incrustation on metal surfaces and are not recommended for industrial use. But there are no corrosion effects from any waters in terms of pH, TDS and Cl concentrations in the study area.

The health risk assessment for NO<sub>3</sub>, As and Cr (separately for dry and wet seasons) was carried out on the grounds. The arsenic concentrations exceeded the limit values. According to the health risk assessment, the study area is categorized as a high risk area.

As a result, the use of Korkuteli district center water resources is not suitable as drinking water. Use of these waters as drinking water will affect human health negatively. Taking this into consideration, precautions must be taken.

## ACKNOWLEDGEMENTS

This work was supported by the Research Fund of the Suleyman Demirel University. Project number: 4720-YL1-16. The support of the General Directorate of State Hydraulic Works (SHW) XVIII Regional Directorate, Isparta is gratefully acknowledged.
