Initial submission October 12, 2008; accepted for publication December 15, 2008.

The authors conducted a cross-sectional study of the association of serum selenium with the prevalence of peripheral arterial disease among 2,062 US men and women 40 years of age or older participating in the National Health and Nutrition Examination Survey, 2003–2004. Serum selenium was measured by using inductively coupled plasma-dynamic reaction cell-mass spectrometry. Peripheral arterial disease was defined as an ankle-brachial blood pressure index < 0.90. The age-, sex-, and race-adjusted prevalence of peripheral arterial disease decreased with increasing serum selenium (P for linear trend = 0.02), but there was an indication of an upturn in risk in the highest quartile of serum selenium. The fully adjusted odds ratios for peripheral arterial disease comparing selenium quartiles 2, 3, and 4 with the lowest quartile were 0.75 (95% confidence interval: 0.37, 1.52), 0.58 (95% confidence interval: 0.28, 1.19), and 0.67 (95% confidence interval: 0.34, 1.31), respectively. In spline regression models, peripheral arterial disease prevalence decreased with increasing serum selenium levels up to 150–160 ng/mL, followed by a gradual increase at higher selenium levels. The association between serum selenium levels and the prevalence of peripheral arterial disease was not statistically significant, although a U-shaped relation was suggested.

Abbreviations: ABI, ankle-brachial blood pressure index; NHANES, National Health and Nutrition Examination Survey.

Selenium, an essential micronutrient involved in antioxidant selenoenzymes such as glutathione peroxidases, has been hypothesized to prevent atherosclerotic disease (1–3). Glutathione peroxidase synthesis and activity, however, plateau at selenium levels above 70–90 ng/mL (4). In the United States compared with other countries, selenium intake is substantially higher (5), and most adults have serum selenium levels above 95 ng/mL (4). At these high concentrations, selenium is incorporated nonspecifically as selenomethionine in the synthesis of other plasma proteins, with unknown health effects (4). It is thus unclear whether increased selenium levels confer additional benefit for atherosclerosis prevention in the United States.

A recent meta-analysis of 14 prospective cohort studies found a modest, but statistically significant inverse association between selenium levels and coronary heart disease (3), but the 2 US studies in this meta-analysis found no association (3, 6, 7). Moreover, serum selenium levels were not associated with cardiovascular disease mortality in a prospective study in a representative US sample, although a U-shaped relation was suggested (8). Given the current interest in selenium supplements for chemoprevention of cancer (5), it is important to understand the overall impact of increased selenium intake on other health endpoints, including vascular disease.

Peripheral arterial disease, which affects about 8 million Americans, is characterized by flow-limiting atherosclerosis...
in the muscular arteries of the lower extremities and is an important marker of generalized atherosclerosis (9–11). Data on the association of selenium levels with peripheral arterial disease are very limited (12, 13). The objective of the present study was to assess the association between serum levels of selenium and reduced ankle-brachial blood pressure index (ABI), a specific subclinical marker for peripheral arterial disease, in the National Health and Nutrition Examination Survey (NHANES), 2003–2004. ABI values below 0.90 are considered diagnostic of peripheral arterial disease. Furthermore, a low ABI is an independent predictor of cardiovascular risk after adjusting for traditional cardiovascular risk factors (14, 15).

MATERIALS AND METHODS

NHANES is conducted by the National Center for Health Statistics (Hyattsville, Maryland) by using a complex multistage sampling design to obtain a representative sample of the civilian, noninstitutionalized US population. We used data from NHANES 2003–2004 (16) because it was the first NHANES survey to measure selenium and ABI levels simultaneously. In NHANES 2003–2004 interviews and physical examinations, the overall response rate was 76%. Serum selenium and ABI measurements were restricted to participants aged 40 years or older (N = 3,086). We excluded 2 pregnant women, 183 participants without selenium measurements, 514 participants without ABI measurements in both legs, and 314 participants with missing information on any adjustment covariate. We finally excluded 11 participants with left or right ABI measurements of more than 1.5, usually due to vessel stiffness. The final sample size was 2,062. The 2003–2004 NHANES study protocols were approved by the National Center for Health Statistics institutional review board. Oral and written informed consent was obtained from all participants.

Serum selenium

Collection materials were screened for potential selenium contamination. After blood collection, serum aliquots were obtained, frozen at −20°C, and shipped to the Trace Elements Laboratory at the Wadsworth Center of the New York State Department of Health for analysis. Serum selenium levels were measured by using inductively coupled plasma-dynamic reaction cell-mass spectrometry. The laboratory procedures and quality control methods for serum selenium measurement have been described in detail elsewhere (17). The between-assay coefficients of variation for quality-control pooled samples analyzed throughout the duration of the survey ranged from 2.5% to 2.9%.

Peripheral arterial disease

A specific protocol was used to measure ABI in NHANES 2003–2004 (18). The measurements of blood pressure used for ABI were additional to and different from other measurements of blood pressure used to evaluate hypertension. Systolic blood pressure was measured on the right arm (brachial artery) and both ankles (posterior tibial arteries) with a Doppler device, the Parks Mini-Lab IV, model 3100 (Parks Medical Electronics, Inc., Aloha, Oregon). If the participant had a condition that would interfere with blood pressure reading in the right arm, the left arm was used. Systolic blood pressure was measured twice at each site for participants aged 40–59 years and once at each site for participants aged 60 years or older. The left and right ABI measurements were obtained by dividing the mean systolic blood pressure in each ankle by the mean systolic blood pressure in the arm. Peripheral arterial disease was defined as an ABI value of less than 0.90 in at least one leg (14, 15).

Other variables

Information about age, sex, race-ethnicity, education, family income, menopausal status for women, cigarette smoking, alcohol consumption, use of dietary supplements, and use of cholesterol- and blood-pressure-lowering medications was based on self-report. Body mass index was calculated by dividing measured weight in kilograms by measured height in meters squared. Three to 4 systolic blood pressure measurements were taken and were averaged by using standardized protocols. Diabetes was defined as a fasting serum glucose concentration of 126 mg/dL or higher, a nonfasting serum glucose concentration of 200 mg/dL or higher, a self-reported physician diagnosis, or current medication use. Glomerular filtration rate was estimated by using the Modification of Diet in Renal Disease Study equation with serum creatinine values (19).

Statistical methods

Participants were grouped in quartiles of serum selenium levels based on the weighted population distribution. Odds ratios and 95% confidence intervals for peripheral arterial disease prevalence comparing the 3 highest quartiles of serum selenium with the lowest quartile were estimated by using logistic regression. Tests for linear risk trend across serum selenium quartiles were performed by including an ordinal variable with the median selenium level of each quartile in the logistic regression models. To further explore the shape of the dose-response relation between serum selenium levels and peripheral arterial disease prevalence, we used restricted quadratic splines with knots at the 5th, 50th, and 95th percentiles of serum selenium distribution. These spline models require the same number of parameters as the quartile analysis, but they can accommodate a wide variety of smooth risk trends (20). Sensitivity analyses using different numbers and locations of the knots, with cubic instead of quadratic splines, and log-transforming serum selenium levels gave similar results (not shown). Statistical analyses were performed with the survey package in R software (to account for the complex sampling design in NHANES 2003–2004) (21, 22). Stratification, primary sampling units, and examination sample weights were used to obtain unbiased point estimates and robust linearized standard errors.
RESULTS

The weighted prevalence of peripheral arterial disease in the study population was 4.9%. Compared with participants without peripheral arterial disease, those with disease were more likely to be older, black, ever smokers, nondrinkers, and diabetic; to have a lower educational level and family income; and to use cholesterol- and blood-pressure-lowering medications (Table 1). Participants with peripheral arterial disease, compared with those without disease, also had higher average levels of body mass index, systolic blood pressure, and C-reactive protein and lower high density lipoprotein cholesterol levels and glomerular filtration rate.

Participants in the highest quartile of serum selenium levels, compared with those in the lowest quartile, were more likely to be older, men, white, and nonsmokers and to use dietary supplements and cholesterol-lowering medications (Table 2). Serum selenium levels were also positively associated with total cholesterol, high density lipoprotein cholesterol, and systolic blood pressure and were inversely associated with body mass index and serum cotinine levels.

The age-, sex-, and race-adjusted prevalence of peripheral arterial disease decreased with increasing serum selenium levels ($P$ for linear trend = 0.02) (Table 3). However, there was an indication of an upturn in risk trend in the highest quartile of serum selenium, particularly after adjusting for cardiovascular risk factors. The fully adjusted odds ratios for peripheral arterial disease comparing selenium quartiles 2, 3, and 4 with the lowest quartile were 0.75 (95% confidence interval: 0.37, 1.52), 0.58 (95% confidence interval: 0.28, 1.19), and 0.67 (95% confidence interval: 0.34, 1.31), respectively. In spline regression models, peripheral arterial disease prevalence decreased with increasing serum selenium levels up to 150–160 ng/mL (80th–91st percentiles of the serum selenium distribution in the study population), followed by a gradual increase at higher selenium levels (Figure 1). Consistently, there was a marginally significant U-shaped dose-response relation between serum selenium...
DISCUSSION

In this cross-sectional study, conducted in a representative sample of the US population, the association between serum selenium levels and the prevalence of peripheral arterial disease was not statistically significant, although a U-shaped relation was suggested: the prevalence of peripheral arterial disease decreased with increasing serum selenium levels up to 150 ng/mL but increased with increasing selenium levels above 160 ng/mL. Selenium intake varies around the world primarily because of geographic variation in the amount of selenium in the soil (1, 23). In the United States, estimated selenium intake ranges from 60 μg/day to 220 μg/day (23), higher than the recommended dietary allowance for healthy adults (55 μg/day) (4). As a consequence, serum selenium levels in the United States are high: in NHANES 2003–2004, the median selenium level was 134 ng/mL, and 99% of study participants had serum selenium levels above 95 ng/mL. These concentrations are considerably higher than in other countries. In Europe, for instance, average serum selenium levels range from 50 ng/mL to 90 ng/mL (23, 24).

Very limited data are available on the association of selenium with peripheral arterial disease. Two small studies found similar selenium levels in patients with peripheral arterial disease compared with controls, but the dose-response relation was not evaluated (12, 13). For other cardiovascular outcomes, most prospective studies have been

a Values are expressed as percentages for categorical variables or means for continuous variables adjusted for age (years), sex, and race-ethnicity; for serum cotinine and C-reactive protein, adjusted geometric means are reported.
b P value for linear trend in percentages or means across quartiles of serum selenium adjusted for age (years), sex, and race-ethnicity.
conducted in populations with suboptimal selenium levels in Europe or China (3, 25–36). These studies tended to report inverse associations between serum selenium levels and coronary heart disease incidence, but their sample sizes were too small for detailed dose-response analyses.

Findings from the only 2 prospective studies of serum selenium levels and coronary heart disease conducted in the United States, however, are consistent with a U-shaped relation (6, 8). In the Physicians’ Health Study, the relative risks for incident myocardial infarction comparing quintiles 2–5 of plasma selenium with the lowest quintile were 0.87, 0.82, 0.60, and 1.53, respectively (6). The cutoff levels for quintiles 1 and 5 of serum selenium in this study were 92 ng/mL and 134 ng/mL, respectively. In the NHANES III Mortality Study, the relative risks for cardiovascular disease mortality comparing tertiles 2 and 3 of serum selenium with the lowest tertile were 0.90 and 0.98, respectively; for stroke mortality, the corresponding relative risks were 0.73 and 1.23 (8). The cutoff levels for serum selenium tertiles in NHANES III were 117.3 ng/mL and 130.4 ng/mL, respectively. In this study, a dose-response analysis showed that cardiovascular and coronary heart disease mortality decreased with increasing serum selenium levels up to 120 ng/mL followed by an increase at higher levels, although the U-shaped relation was not statistically significant (8). Finally, in the Health Professionals Follow-up Study, the odds ratios for incident coronary heart disease comparing quintiles 2–5 of toenail selenium levels with the first quintile were 1.03, 0.99, 1.32, and 0.86, respectively, with no clear dose-response relation (7). Both serum and toenail selenium levels reflect selenium status, although toenails reflect longer-term exposure. It is unclear, however, whether both biomarkers are comparable in their ability to capture the different types of selenium compounds.

Few randomized trials have evaluated the effect of selenium supplementation on cardiovascular outcomes or atherosclerosis progression, and most of these studies combined selenium with other vitamins and minerals (3, 37). Only 2 of these trials were conducted in the United States, both reporting null results (38, 39). In the Nutritional Prevention of Cancer trial, the relative risk for cardiovascular disease incidence comparing
200 μg/day of selenium supplementation with placebo was 1.03 (95% confidence interval: 0.78, 1.37) (38). In the HDL-Atherosclerosis Treatment Study, the progression of atherosclerosis measured by coronary angiography in patients with coronary artery disease was similar among participants randomized to an antioxidant supplement containing 100 μg/day of selenium, 800 IU/day of vitamin E, 1 g/day of vitamin C, and 25 mg/day of β-carotene and participants randomized to placebo (39). Overall, limited evidence from randomized trials has not shown a protective effect of selenium supplementation in US studies. With respect to observational studies, those in the United States have not been able to detect a significant linear association between serum selenium and cardiovascular outcomes, but the dose-response associations in these studies were U-shaped.

The biologic mechanisms underlying a potential effect of selenium on cardiovascular disease are likely complex, but they may be related to the dual role of selenium as an essential and toxic element. Selenium is an essential micronutrient that is incorporated into glutathione peroxidases and other selenoproteins (4). Increasing serum selenium levels increase the concentration and activity of glutathione peroxidases, but this dose-response relation reaches a plateau at serum selenium levels of 70–90 ng/mL (4). As a consequence, higher selenium levels could potentially prevent atherosclerosis development and progression in populations whose selenium exposure is below the levels needed to maximize glutathione peroxidases (1–3). In selenium-replete populations such as in the United States, in which virtually all participants have serum selenium levels above 70–90 ng/mL, the mechanisms underlying a potential beneficial effect of increased selenium levels are unclear. Since selenium supplementation is actively promoted in the United States, and large randomized controlled trials testing the efficacy of selenium supplementation in prostate cancer prevention are under way (40, 41), mechanistic studies are urgently needed to establish the biologic basis for a protective effect of selenium in populations whose selenium status is already high.

Selenium, however, has a narrow therapeutic range (4), and it may even be harmful at intake levels below the current tolerable Upper Intake Level of 400 μg/day (2). In fact, some selenium compounds have been documented to generate reactive oxygen species (42–44), and the upturn in peripheral arterial disease prevalence that we observed at serum levels above 160 ng/mL could be associated with selenium-induced increased oxidative stress. This upturn in risk is also consistent with recent reports showing increased risk of diabetes (45, 46) and elevated lipid levels (47) with high selenium levels in US populations. For instance, the Nutritional Prevention of Cancer trial showed an increased risk of diabetes for participants receiving 200 μg/day of selenium compared with placebo (hazard ratio = 1.50, 95% confidence interval: 1.03, 2.33) (46). Interestingly, the excess risk was limited to participants in the upper tertile of the serum selenium distribution (≥121.6 ng/mL), who had a hazard ratio for diabetes of 2.70 (95% confidence interval: 1.30, 5.61). Further research is needed to establish the mechanisms underlying the association of high-normal selenium levels with peripheral arterial disease and with metabolic abnormalities, and to determine whether the change point in risk associated with elevated selenium levels depends on genetic polymorphisms in candidate genes for selenium metabolism (48).

Several limitations of our study need to be considered. The use of a cross-sectional design and of prevalent cases of peripheral arterial disease limited our ability to determine the direction and the causality of the observed association. It is possible that the pathophysiologic changes of atherosclerosis could modify serum selenium levels or that participants with peripheral arterial disease change their health behaviors, including selenium intake through diet and dietary supplements. As a consequence, our findings must be confirmed in prospective studies with incident cases of peripheral arterial disease. Another limitation of our study is the use of a single measurement of serum selenium, which reflects short-term selenium intake and may be subject to high within-person variability (49). Furthermore, our study measured only total serum selenium, and we did not have information on selenoprotein levels or activity or about non-specific incorporation of selenium as selenomethionine in other plasma proteins. More detailed analysis of different compartments of serum selenium will be needed to better understand the association of selenium with peripheral arterial disease. The strengths of our study come from the rigorous sampling design and the quality of the study measurements used in NHANES; the representativeness of the NHANES sample; and the use of ABI, a noninvasive measure of subclinical atherosclerosis.

In summary, the association between serum selenium levels and the prevalence of peripheral arterial disease in NHANES 2003–2004 was not statistically significant, although a U-shaped relation was suggested. Other sources of evidence (6, 8) also suggest a U-shaped relation between serum selenium levels and cardiovascular outcomes in the United States, a selenium-replete population. In many populations worldwide, selenium intake is lower than in the United States (1, 23). At these lower levels of selenium intake, the association of selenium with peripheral arterial disease remains unknown. Prospective studies of selenium status across populations with different levels of selenium intake and randomized trials stratified by baseline selenium status are needed to establish the optimal selenium levels to minimize the risk of cardiovascular and other chronic diseases.
