ABSTRACT

We present radio observations at frequencies ranging from 240 to 8460 MHz of the radio galaxy 4C 29.30 (J0840+2949) using the Giant Metrewave Radio Telescope (GMRT), the Very Large Array (VLA) and the Effelsberg telescope. We report the existence of weak extended emission with an angular size of ~520 arcsec (639 kpc) within which a compact edge-brightened double-lobed source with a size of 29 arcsec (36 kpc) is embedded. We determine the spectrum of the inner double from 240 to 8460 MHz and show that it has a single power-law spectrum with a spectral index of ~0.8. Its spectral age is estimated to be ~200 Myr, suggesting that the extended diffuse emission is due to an earlier cycle of activity. We re-analyse archival X-ray data from Chandra and suggest that the X-ray emission from the hotspots consists of a mixture of non-thermal and thermal components, the latter being possibly due to gas which is shock heated by the jets from the host galaxy.

Key words: galaxies: active – galaxies: individual: 4C 29.30 – galaxies: nuclei – radio continuum: galaxies.

1 INTRODUCTION

One of the interesting issues in our understanding of active galactic nuclei (AGN) is the duration of their active phase and whether such activity is episodic. In radio galaxies and quasars the extended radio emission provides us with an opportunity to probe their history via the structural and spectral information of the lobes. A striking example of episodic nuclear activity is when a new pair of radio lobes is seen closer to the nucleus before the ‘old’ and more distant radio lobes have faded (e.g. Subrahmanyan, Saripalli & Hunstead 1996; Lara et al. 1999). Such sources have been christened as ‘double–lobes have faded (e.g. Subrahmanyan, Saripalli & Hunstead 1996; Lara et al. 1999). Such sources have been christened as ‘double–

...
sources (e.g. Reich et al. 1980; Stute, Reich & Kalberla 1980; Perley, Fomalont & Johnston 1982; Kronberg & Reich 1983; van der Laan, Zieba & Noordam 1984; Jones & Preston 2001).

In this paper we concentrate on the radio galaxy 4C 29.30 (J0840+2949) which is associated with a bright ($R \sim 15$ mag) host elliptical galaxy (RA 08h40m02.370, Dec. +29°49′02″60′′; all positions being in J2000 coordinates throughout the paper) at a redshift of $0.06471 \pm 0.00013$. The corresponding luminosity distance is 287 Mpc and 1 arcsec corresponds to 1.228 kpc in a Universe with $H_0 = 71$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.27$, $\Omega_{\Lambda} = 0.73$ (Spergel et al. 2003). The published images show a double-lobed radio source which has two prominent hotspots at the outer edges with an overall angular separation of 29 arcsec (36 kpc) and a prominent jet towards the south-west (e.g. Parma et al. 1986; van Breugel et al. 1986, and references therein). In addition there is a diffuse blob of emission towards the south-west (SW blob) with a size of $\sim$40 arcsec (50 kpc) extending beyond the south-western hotspot. The radio luminosity of the inner double at 1400 MHz is $5.5 \times 10^{24}$ W Hz$^{-1}$, which is significantly below the dividing line of the Fanaroff–Riley (FR) classes, while that of the entire source is $7.4 \times 10^{25}$ W Hz$^{-1}$. It is interesting to note that in some of the DDRGs, the luminosity of the inner double is in the FR-I category although its structure resembles that of FR-II radio sources (cf. Saikia et al. 2006). A detailed radio and optical study of this galaxy (van Breugel et al. 1986) shows optical line-emitting gas adjacent to the radio jet along a position angle (PA) of $\sim 20^\circ$ and evidence of the radio jets interacting with dense extranuclear gas.

The host galaxy of 4C 29.30 appears to have merged with a gas-rich galaxy, shows presence of shells and dust (Gonzalez-Serrano, Carballo & Perez-Fournon 1993) and is associated with an IRAS source F08369+2959 (Keel et al. 2005). At X-ray wavelengths Chandra detects emission from the hotspots in the south-western radio lobe and also in the counterlode (Gambill et al. 2003; Sambruna et al. 2004). Both hotspots have also been detected in observations with the Hubble Space Telescope (Sambruna et al. 2004).

In this paper we show the presence of diffuse extended emission on an angular scale of $\sim 520$ arcsec (639 kpc) which could be due to an earlier cycle of activity, from observations with the Very Large Array (VLA), the Giant Metrewave Radio Telescope (GMRT) and the Effelsberg telescope. This feature is also visible clearly in the Westerbork Northern Sky Survey (WENSS; Rengelink et al. 1997) at 325 MHz and the NRAO VLA Sky Survey (NVSS; Condon et al. 1998) at 1400 MHz. We also present multifrequency observations of the inner double and the diffuse SW blob of emission with the GMRT and the VLA. This should enable us to determine the spectrum more reliably and estimate the spectral ages and perhaps constrain the time-scales of episodic activity in this source. For example, in the DDRG J1453+3308 we have been able to show using both GMRT and VLA observations that the spectrum of the outer lobes exhibits significant curvature while that of the inner lobes appears practically straight (Konar et al. 2006).

Our multifrequency observations and data reduction are described in Section 2. The observational results such as the radio maps showing the source structure and spectra are presented in Section 3. The results are presented in Section 4, while the concluding remarks are given in Section 5.

### 2 OBSERVATIONS AND DATA REDUCTION

The analysis presented in this paper is based on radio observations made with the Effelsberg telescope, GMRT and VLA, as well as on VLA archival data. The observing log for the GMRT and VLA as well as Effelsberg observations is listed in Table 1 which is arranged as follows. Columns 1 and 2 show the name of the telescope and the array configuration for the VLA observations; columns 3 and 4 show the frequency and bandwidth used in making the images; column 5 shows the primary beamwidth in arcmin; column 6 shows dates of the observations. The phase centre for all the observations was near the core of the radio galaxy except for the VLA CnD array observations at 5 GHz where the antennas were pointed about 2 arcmin north and south of the core in an effort to detect the diffuse extended emission.

#### 2.1 GMRT observations

The observations were made in the standard manner, with each observation of the target source interspersed with observations of either J0735+331 or J0741+312 which was used as a phase calibrator. 3C 48 was observed as a flux density and bandpass calibrator. At each frequency the source was observed in a full-synthesis run of approximately 9 h including calibration overheads. The r.m.s. noise in the resulting full-resolution images ranges from about 1 mJy beam$^{-1}$ at 240 MHz to about 0.06 mJy beam$^{-1}$ at 1287 MHz. Details about the array can be found at the GMRT website at http://www.gmrt.ncra.tifr.res.in. The data collected were calibrated and reduced in the standard way using the NRAO AIPS software package. Several rounds of self-calibration were done to improve the quality of the images. The absolute position uncertainty could be up to several arcsec in the low-frequency images due to phase errors introduced by the ionosphere (cf. Rengelink et al. 1997). The flux densities at the different frequencies are consistent with the scale of Baars et al. (1977).

#### 2.2 New and archival VLA observations

The source was observed with the CnD array at a frequency of 4860 and 8460 MHz to determine the spectra over a large frequency range by combining these results with those from the low-frequency GMRT images. The source was observed in the snapshot mode, the integration time for each scan being $\sim 20$ min. At 4860 MHz the source was also observed with the phase centres shifted by $\sim 2$ arcmin towards the north and south of the core to image the diffuse extended emission. The interferometric phases were calibrated with the phase calibrator J0830+241. The source 3C 286 was used as the primary flux density calibrator. For the images produced from the data sets where the phase centres have been shifted...
by \sim 2\text{arcmin}, correction for the primary beam pattern has been done. We also supplemented our observations with VLA archival data to examine evidence of variability of the core and determine the spectrum of the inner double-lobed source. These observations were made with the C-array at 4860 MHz.

We retrieved the \(L\)-band data of 4C 29.30 from the VLA archive. The unpublished observations (proposal number AL515) were carried out in the D-array configuration using the ‘correlator mode 4’ with a bandwidth of 25 MHz and central frequencies of 1365 and 1435 MHz. The observations were performed in two runs on 2001 November 30 and 2001 December 24 with the pointing centre at RA 08\text{h}40\text{m}02\text{s}, Dec. +29 \text{\degree}49\text{\arcmin}03\text{\arcsec} and a total integration time of \(2 \times 50\text{min}\). The telescope gains were calibrated using the calibration source 3C 147. The source J0741+312 was used as a phase calibrator. After the initial data reduction the two data sets were merged using the task \textsc{dbcon}. After preliminary CLEANing of the map with the routine \textsc{imagr}, several self-calibrations were performed to improve its quality. Finally, the map was corrected for primary beam attenuation. As in the case of the GMRT data, all the VLA data were edited and reduced using the \textsc{AIPS} package. All flux densities are on the Baars et al. (1977) scale.

2.3 Effelsberg observations

The 4850-MHz observations of 4C 29.30 were carried out on 2004 June 25 with the two-horn receiver system (Thierbach, Klein & Wielebinski 2003) at the secondary focus of the Effelsberg 100-m telescope. A total of six coverages, with a size of 20 \times 20\text{arcmin}^2 in azimuth and elevation, were obtained. The scanning speed was \(40\text{arcmin\,min}^{-1}\) and the scan separation 1\text{arcmin}. Calibration and pointing performance of the system were checked by mapping and cross-scanning the point-like sources, 3C 286 and B0851+20. We adopt the flux density scale of Baars et al. (1977). The standard Max-Planck-Institut fü R Radioastronomie (MPIfR) \textsc{nod2} (Haslam 1974) software package was used for the data reduction. First, all single-pixel noise spikes were removed by hand from each of the scans. Then the individual maps were combined using the \textsc{plait} algorithm by Emerson & Gräve (1988). The rms noise of 0.9 mJy beam\(^{-1}\) in total power was estimated from off-source regions of the image well away from its edges and the half-power beamwidth was determined to be 144.5\text{arcsec}. Finally, the NRAO \textsc{AIPS} software package was used for imaging the source.

3 OBSERVATIONAL RESULTS

3.1 Overall structure

Our VLA image at 1400 MHz with an angular resolution of \sim 45\text{arcsec} (Fig. 1) shows the entire structure of 4C 29.30 which has a largest angular extent of 520\text{arcsec} (639 kpc), in addition to the inner structure with an angular size of 29\text{arcsec} (36 kpc). The rms noise in the image is 0.13 mJy beam\(^{-1}\) while the total flux density is 756 mJy. There is a peak of emission with a peak brightness of 10 mJy beam\(^{-1}\) located at RA 08\text{h}40\text{m}04\text{s}, Dec. +29 52\text{\arcmin}04\text{\arcsec} in the northern region of the extended emission which is brighter than the south which has a peak brightness of \sim 3.5 mJy beam\(^{-1}\) at
RA 08\textsuperscript{h}39\textsuperscript{m}59\textsuperscript{s}29, Dec. +29\textdegree}46\arcmin32\arcsec. We have reproduced in Fig. 1 the FIRST (Faint Images of the Radio Sky at Twenty-cm; Becker, White & Helfand 1995) image of the source with an angular resolution of 5.4 arcsec which shows the inner double-lobed structure and the SW blob of emission. Because of lack of short baselines this VLA B-array survey is insensitive to the extended structures.

The diffuse extended structure can also be seen in our Effelsberg image at 4850 MHz as well as the WENSS image at 325 MHz and the NVSS image at 1400 MHz (Fig. 2). The 325-MHz WENSS map of the total intensity emission of 4C 29.30 with the angular resolution of about 54 × 109 arcsec\(^2\) (Fig. 2a) has an rms noise of 3.9 mJy beam\(^{-1}\) while the total flux density of the entire source is 2170 mJy. The total intensity 1400-MHz VLA D-array NVSS map of the source with an angular resolution of 45 × 45 arcsec\(^2\) and an rms noise of 0.45 mJy beam\(^{-1}\) (Fig. 2b) has a total flux density of 731 mJy, which is only marginally smaller than the estimate of 756 mJy from our image (Fig. 1).

Although only the inner double and the SW blob of emission are visible in the full-resolution GMRT images as discussed below, tapered images with an angular resolution of 45 arcsec were made from the GMRT data at 240, 333, 605 and 1287 MHz to detect the diffuse extended emission. These images are presented in Fig. 3 and have an rms noise of 4.6, 1.6, 0.9 and 0.5 mJy beam\(^{-1}\), respectively, while the total flux densities are 3541, 2647, 1465 and 727 mJy, respectively. A comparison of the GMRT low-resolution images with our VLA D-array image (Fig. 1) shows that although the northern peak and some diffuse emission have been detected, weaker diffuse emission have been missed in these images. While at the lower frequencies this is due to the higher rms noise values, the flux density at 1287 MHz could also be affected by the lack of short spacings.

### 3.2 The inner structure

The inner structure of 4C 29.30 has been observed several times at different frequencies, viz. at ∼1400 MHz (Fanti et al. 1977; Parma et al. 1986; van Breugel et al. 1986; Capetti et al. 1993), ∼5000 MHz (Fanti et al. 1977; van Breugel et al. 1986; Giovannini et al. 1988) and ∼15 000 MHz (van Breugel et al. 1986). The maps show two arrow-shaped lobes. The more compact, northern lobe is located close to the radio core while the southern one, which is connected with the nucleus by a distinct radio jet, is more extended. The inner double-lobed structure is oriented along a PA of ∼26\degree which is misaligned from the outer extended emission by ∼18\degree. The outer emission is oriented close to that of the optical filament towards the south noted by van Breugel et al. (1986).

The GMRT low-frequency images at 240, 333, 605 and 1287 MHz which show the inner double and the SW blob of emission are shown in Figs 4 and 5, while the VLA images at 4860 and 8460 MHz are presented in Fig. 6. The flux densities estimated from these images are listed in Tables 2 and 3. The observational parameters and some of the observed properties are presented in Table 2, where we list the values estimated from the full-resolution images as well as those estimated from the images made by tapering and weighting the data to match the resolution of the GMRT image at 240 MHz. Table 2 is arranged as follows. Column 1: frequency of observations in MHz, with the letter G or V representing either GMRT or VLA observations; columns 2–4: the major and minor axes of the restoring beam in arcsec and its PA in degrees; column 5: the rms noise in units of mJy beam\(^{-1}\); column 6: the peak flux density in the image in units of mJy beam\(^{-1}\); column 7: the total flux density of only the inner double in units of mJy; column 8: the total flux density of the inner double along with its small extension to the south-west in units of mJy. The flux densities have been estimated by specifying a polygon around the source. The error in the flux density is approximately 15 per cent at 240 MHz and 7 per cent at the higher frequencies.
3.3 The radio core

Our higher resolution images (Figs 5 and 6) clearly show the radio core in addition to the lobes of radio emission. The J2000.0 position of the radio core estimated from our high-resolution image at 8460 MHz is RA 08h40m02.35, Dec. +29°49′02.5″, which is consistent with the position of the optical galaxy (RA 08h40m02.370, Dec. +29°49′02.60″) from NASA/IPAC Extragalactic Database (NED). van Breugel et al. (1986) and Giovannini et al. (1988) have reported observations of this source with the VLA A-array. These observations confirm the presence of the radio core in addition to the extended lobes.

Figure 3. The GMRT images of 4C 29.30 at 240 MHz (upper left), 333 MHz (upper right), 605 MHz (lower left) and 1287 MHz (lower right). All these images have been made with an angular resolution of 45 arcsec which is shown as a circle in the top right-hand corner.
subarcsec-resolution images show a compact core and a radio jet towards the south-west with a prominent knot in the jet separated from the core by \( \sim 3 \) arcsec (3.7 kpc). With our relatively coarse resolution of a few arcsec, the core flux density is contaminated by emission from the jet. From the high-resolution observations the core flux density is 10.4 mJy at 4873 MHz and 8.2 mJy at 4860 MHz (van Breugel et al. 1986; Giovannini et al. 1988), although the flux density including the knot is \( \sim 16.5 \) mJy.

Although our observations are of different resolutions, we have attempted to examine evidence of variability by making images with an angular resolution of 5.4 arcsec along the jet axis, which is similar to the resolution of the FIRST image, so that contamination by emission from the jet is similar at the different frequencies. A comparison of the flux densities in 2005 suggests that there was a strong outburst between about 1990 and 2005 which is apparent in the core flux densities at 4860 and also possibly at \( \sim 1300 \) MHz (Fig. 7).

**Figure 4.** The GMRT images of 4C 29.30. Left-hand panel: image at 240 MHz with an angular resolution of 13.8 \( \times \) 11.1 arcsec\(^2\) along PA 64\(^\circ\). Right-hand panel: the 333-MHz image with an angular resolution of 10.6 \( \times \) 8.5 arcsec\(^2\) along PA 68\(^\circ\). The resolution is shown as an ellipse in the bottom left-hand corner while the + sign marks the position of the optical galaxy.

**Figure 5.** The GMRT images of 4C 29.30. Left-hand panel: image at 605 MHz with an angular resolution of 5.66 \( \times \) 4.50 arcsec\(^2\) along PA 66\(^\circ\). Right-hand panel: image at 1287 MHz with an angular resolution of 2.97 \( \times \) 2.30 arcsec\(^2\) along PA 46\(^\circ\). The resolution is shown as an ellipse in the bottom left-hand corner while the + sign marks the position of the optical galaxy.
Intermittent jet activity in 4C 29.30?

Figure 6. Left-hand panel: the VLA image of 4C 29.30 at 4860 MHz with an angular resolution of 4.13 \times 3.90 \text{arcsec}^2 along PA 162°. Right-hand panel: the VLA image at 8460 MHz with an angular resolution of 7.90 \times 2.46 \text{arcsec}^2 along PA 78°. The resolution is shown as an ellipse in the bottom left-hand corner while the + sign marks the position of the optical galaxy.

It is relevant to note that in the DDRG J1453+3308 Konar et al. (2006) reported evidence of significant variability of the core flux density at centimetre wavelengths. Other examples of cores which have been monitored and show evidence of variability are 3C 338 and B2 1144+352 (Giovannini et al. 1998, 1999; Schoenmakers et al. 1999). It is interesting to note that both these objects are possible examples of episodic jet activity (cf. Burns et al. 1983a; Schoenmakers et al. 1999). It is important to determine from more extensive monitoring whether strong core variability may be a common characteristic of sources with renewed jet or nuclear activity even if the cores are relatively weak. However, it is also relevant to note that strong core variability and superluminal motion may be seen in sources inclined at small angles to the line of sight. Such sources are also expected to have dominant cores due to Doppler boosting of the core flux density. Amongst the sources discussed here, the arcsec scale core in B2 1144+352 contributes almost 80 per cent of the total observed flux density at 1400 MHz, while for the other three objects it contributes \(<5\) per cent, similar to other galaxies of comparable luminosity (cf. Saikia & Kulkarni 1994; Ishwara-Chandra & Saikia 1999). This is consistent with the detection of superluminal motion in B2 1144+352 (Giovannini et al. 1999), while 3C 338 exhibits two reasonably symmetric parsec-scale jets and evidence of subluminal motion (Giovannini et al. 1998). The cores of 4C 29.30 and J1453+3308 are weak and have not been studied with mas (milliarcsec) resolution.

### 3.4 Spectra

The flux densities of the source, 4C 29.30, from the literature as well as from our images which show the extended structure (Figs 1,
The core flux densities from our data and FIRST are peak values in units of mJy. The values within brackets are from images made with an angular resolution of 5.4 arcsec approximately along the jet axis so that the contamination from jet emission is similar. The diffuse extended emission is visible in these images (Figs 1, 2 and 3), although the entire flux density is possibly seen only in the VLA D-array image at 1400 MHz (Fig. 1) and the Effelsberg image at 4850 MHz (Fig. 2).

The diffuse extended emission is more likely to make a significant contribution to the total flux density at 1452 MHz, which is listed in the table here. The flux density of C+ from images which have been tapered and weighted to have the same resolution as that of the 240-MHz image. The core contribution is subtracted for the flux densities at 4850 MHz (Fig. 2).

3.5 Polarization properties

The distributions of the 1400 and 4850 MHz linear polarization of 4C 29.30 are shown in Table 4. The linear least-squares fit has been made using measurements only between 240 and 4850 MHz. Lower panel: spectrum of the inner double using our GMRT and VLA images between 240 and 8460 MHz. The contributions of the core component within a region of ~4 arcsec (4.9 kpc) have been subtracted at frequencies ≥1300 MHz. The spectrum shows the low-frequency measurements at 74, 151 and 178 MHz listed in Table 4, although the linear least-squares fit has been made using measurements only between 240 and 8460 MHz. This fit has been extrapolated to lower frequencies.

4 DISCUSSION

4.1 Spectral ageing analysis

The spectra using the total flux densities between 240 and 4860 MHz and that of the inner double using our measurements between 240 and 8460 MHz are consistent with a single power law. We have fitted the spectrum of the inner double after subtracting the core flux density for the Jaffe–Perola (JP; Jaffe & Perola 1973), Kardashev–Pacholczyk (KP; Kardashev 1962; Pacholczyk 1970) and the continuous injection (CI; Pacholczyk 1970) models using the SYNAGE package (Murgia 1996). The break frequency obtained from these fits is rather large (≥7 × 10^8 GHz) and have huge uncertainties because the spectrum is practically straight. These conclusions remain unaffected even if the flux density at 74 MHz is included in the analysis.

In order to calculate the global mean magnetic field strength and estimate the spectral age we have adopted the formula given by Miley (1980), a spheroidal and cylindrical geometry for the diffuse extended emission and the inner double, respectively, a filling factor of ~1, a proton to electron energy ratio of unity and lower- and higher frequency cut-offs of 10 MHz and 100 GHz, respectively. The equipartition magnetic field estimate for the inner double is 0.43 ± 0.06 µG, indicating that for the above-mentioned break frequency the inferred age is ≤0.12 Myr. (For conversion of the magnetic field to µG which is also commonly used, 1 µG = 10 µG.) However, adopting a more conservative break frequency of ≥10 GHz from the observed spectrum, the spectral age is ≤33 Myr.
We have attempted to determine the spectrum of the diffuse extended emission by subtracting the flux density of the inner double from that of the total emission in the images where this is reliably seen. For this purpose we have used our low-resolution GMRT images at 240, 333 and 605 MHz, our VLA D-array and NVSS images at 1400 MHz and our Effelsberg measurements at 4850 MHz to represent the total flux density of the source. Our GMRT image at 333 MHz has a better rms noise than the WENSS image and gives a larger value of the total flux density. After subtracting the contribution of the inner double-lobed source, estimated from our GMRT and VLA images of similar angular resolution of ~12 arcsec, we plot the spectrum of the diffuse emission in Fig. 11. Although there are significant uncertainties, a least-squares fit yields a spectral index of 1.26 ± 0.07. However, given the possibility that we are still missing significant amounts of flux density at the lower frequencies, as discussed earlier, the spectral index could be steeper. Making a very rough estimate of the possible increase in the flux density by assuming that the diffuse emission not detected at the low frequencies compared with the VLA D-array image (Fig. 1) is just below the first contour level yields a spectral index of 1.34 ± 0.05 for the diffuse emission. These points are indicated by open circles in Fig. 11. The above two values are consistent within the errors. These estimates suggest that the halo is likely to be much older than the inner double.

We have also estimated the spectral index from 240 to 1400 MHz in the vicinity of the peak in the northern diffuse emission by considering a box with a size of ~150 arcsec centred on the peak in the 45-arcsec resolution images. The flux densities at 240, 333, 605 and 1400 MHz are 188 ± 26, 139 ± 19, 87 ± 6 and 44 ± 3 mJy, respectively. A least-squares fit yields a spectral index of 0.81 ± 0.01 for this region, which is similar to the spectral index of the inner double, suggesting that this value might be close to the injection spectrum, which is rather steep. The magnetic field strength in the vicinity of the peak in the northern diffuse emission is 0.12 ± 0.02 nT. The straight spectrum of this region till ~1400 MHz yields a spectral age of ≲100 Myr, consistent with an interruption of activity for ≲100 Myr. For the diffuse extended emission, the spectral break is likely to be lower than ~240 MHz, which yields a spectral age ≥200 Myr. To get a reliable value of the spectral break and estimate the age using SYNAGLE we need more sensitive images at low frequencies, especially below ~240 MHz.

Nevertheless, while interpreting these numbers caveats related to the evolution of the local magnetic field in the lobes need to be borne in mind (e.g. Rudnick, Katz-Stone & Anderson 1994; Jones, Ryu & Engel 1999; Blundell & Rawlings 2000). While Kaiser, Schoenmakers & Röttgering (2000) have suggested that spectral and dynamical ages are comparable if bulk backflow and both radiative and adiabatic losses are taken into account in a self-consistent manner, Blundell & Rawlings (2000) suggest that this may be so only in the young sources with ages much less than 10 Myr. More recently Machalski et al. (2007) have examined the dynamical ages of FR-II radio sources and find that while these agree with the spectral ages for objects less than 10 Myr, their method may be applicable for older sources as well. For all objects they find realistic jet advance velocities.
4.2 X-ray observations of the inner double

The existing Chandra data for 4C 29.30 obtained on 2001 April 8 [Observation ID (ObsID) = 2135, previously analysed by Gambill et al. 2003; Sambruna et al. 2004] reveal X-ray emission associated with the inner radio structure. Although the photon statistics from the archival 7.5-ks exposure is very low, several X-ray components are visible, namely a highly obscured nucleus, a diffuse galactic-scale halo, hotspot (‘HS’), counter-hotspot (‘C-HS’) and possibly both jets connecting hotspot and counter-hotspot with the nucleus. There is also a possible X-ray excess to the south-west from the nucleus, cospatial with a region of enhanced optical-line emission.

We reprocessed the archival Chandra data using CALDBv.3. The 7.7-ks Advanced CCD Imaging Spectrometer (ACIS-S) observation detected a total of 123 ± 11 counts from the core (a circle of 1.5-arcsec radius). Most of these counts (105) exceed 2-keV energies, which indicate a very hard spectrum. The absorbed power-law model fit shows strong evidence for large intrinsic absorption of \( N_H \sim (3.5 \pm 0.9) \times 10^{23} \text{cm}^{-2} \) for the fixed photon index of \( \Gamma = 1.7 \), implying the intrinsic unabsorbed luminosity of \( L_{2-10\text{keV}} \sim 3 \times 10^{37} \text{erg s}^{-1} \). This is in agreement with the results by Gambill et al. (2003), although our number of total detected counts is larger because we used the updated Chandra calibration to process the data. Such high values of column density have been reported for some compact radio sources (e.g. Guainazzi et al. 2006; Vink et al. 2006). We note that the nucleus of 4C 29.30 reveals optical features typical of Seyfert 2 and narrow-line radio galaxies (van Breugel et al. 1986).

Both hotspot and the counter-hotspot regions are pronounced in X-rays (Sambruna et al. 2004). Note that low-power radio galaxies like 4C 29.30 usually do not exhibit strong shocks at the terminal regions of the jets. The Chandra data indicate significant differences in the spectra of both features. In particular, in the case of the hotspot the number of soft (0.5–2 keV) and hard (2–10 keV) total counts is \( S = 16 (B = 1) \), where \( B \) indicates background counts, and \( H = 6 (B = 1) \), respectively, giving the hardness ratio \( S/H = 2.9_{-1.3}^{+3.9} \). In the case of the counter-hotspots the analogous numbers are \( S = 9 (B = 1) \), \( H = 1 (B = 1) \) and \( S/H = 10.5_{-3.5}^{+5.5} \) (see Park et al. 2006, for the description of the Bayesian models we used to calculate the hardness ratio and errors). This suggests that the observed hotspot-related X-ray emission, especially in the counter-hotspot, may be a mixture of the thermal and non-thermal radiation. The thermal scenario may be particularly relevant for the counter-hotspot region, which is in fact cospatial with a zone of strong optical line emission. It is interesting to note that in the radio galaxy Cen A, sharing many morphological similarities with the object discussed here, Kraft et al. (2003) reported detection of thermal X-ray emission at the counter-jet termination region due to galactic gas compressed by the expanding radio outflow. We suggest that the Chandra data may indicate similar jet/ambient medium interactions in the counter-hotspot of 4C 29.30, although deeper observations are needed to confirm such a scenario.

In this context it is relevant to note that the line-emitting gaseous filaments extending along the inner radio structure seem to be heated and accelerated by the expanding jet rather than photoionized by the ambient medium (van Breugel et al. 1986). Evidence of similar jet-cloud interactions have been reported for many radio sources such as the compact steep-spectrum sources 3C 48 (Gupta, Srianand & Saikia 2005) and 3C 67, 277.1 and 303.1 (O’Dea et al. 2002).

Another interesting constraint is offered by the polarization studies. As discussed previously, the polarized flux density from the central parts of 4C 29.30 is most likely dominated by the inner lobes. As argued by van Breugel et al. (1986), large differences between the orientations of the E-vectors in this region when observed at 1400 and 4850 MHz suggest Faraday rotation effects, most likely not due to the observed optical emission-line gaseous clouds, but rather due to the ‘intercloud medium’. However, similar rotation of the electric field vector is observed by us also in the outer regions, far (>100 kpc) beyond the inner radio structure studied by van Breugel et al. This may suggest that the Faraday screen should not be identified with the gaseous medium cospatial with the inner (∼few kpc-scale) optical line-emitting clouds, but rather with the ambient thermal gas on larger scales, pushed-out and compressed by the expanding fossil halo, eventually partly mixed with the plasma of the lobes.

5 CONCLUDING REMARKS

We present the results of multifrequency radio observations of the radio galaxy 4C 29.30 using the GMRT, the VLA and the Effelsberg telescope.

(i) The low-resolution images with the VLA, GMRT and the Effelsberg telescope show evidence of large-scale diffuse emission with an angular scale of ∼520 arcsec (639 kpc) in addition to the small-scale inner double which has an angular size of ∼29 arcsec (36 kpc). The structure of the inner double is similar to that of FR-II radio sources although its radio luminosity is in the FR-I category. This is similar to some of the inner doubles in the DDRGs.

(ii) The GMRT and VLA observations of the inner double show that it has a spectral index of ∼0.8 with no evidence of curvature in its spectrum from 240 to 8460 MHz, suggesting that the inner double which has an edge-brightened structure is young. We have fitted the spectrum using SYNAGE for the JP, KP and CI models. The break frequency is large (∼10 GHz) but this value has huge uncertainties because the spectrum is practically straight. Its equipartition magnetic field is 0.43 ± 0.06 nT using the classical formula. The inferred spectral age for the inner double for a conservative lower limit of ∼10 GHz for the break frequency is ≲33 Myr.

(iii) The diffuse outer emission represents emission from an earlier cycle of activity. Its total spectrum is steep with a spectral index of ∼1.3, with the break frequency being ≲240 MHz. Using the classical formula the equipartition magnetic field is 0.07 ± 0.01 nT which yields a radiative age of ≲200 Myr.

(iv) The spectral index for the inner double as well as in the vicinity of the northern peak of the diffuse extended emission is ∼0.8, suggesting that the injection spectral index is close to this value. Although the injection spectrum is somewhat steep, the similarity for the inner double and the outer diffuse emission is reminiscent of J1453+3308 where the outer and inner doubles have similar injection spectral indices (Komar et al. 2006).

(v) The magnetic field in the vicinity of the northern peak of the diffuse extended emission is 0.12 ± 0.02 nT. Given its straight spectrum between 240 and 1400 MHz, this yields a spectral age of ≲100 Myr. Although higher frequency observations are required to extend the spectrum for both the inner double and the diffuse extended emission, the present data suggest a time-scale of interruption of activity of ≲100 Myr. However, the known caveats regarding estimation of spectral ages should be borne in mind.

(vi) The radio core exhibits evidence of variability. This is similar to that of the DDRG J1453+3308, suggesting that significant core variability may often occur in galaxies with evidence of recurrent activity.
The hotspots of the inner double have been detected at X-ray and optical wavelengths using the Chandra X-ray Observatory and the Hubble Space Telescope. Our re-analysis of the X-ray data suggests that the counter hotspot consists of both thermal and non-thermal material. The thermal X-ray emission may be due to hot gas compressed by the expanding radio-emitting outflow on kpc scales.

ACKNOWLEDGMENTS

We thank the anonymous referee for his valuable comments which made us re-look at our data, and present a more satisfactory interpretation of the results. We also thank Bill Cotton and Ger de Bruyn for clarifications on the VLSS and WENSS flux density scales, and Julia Riley and Dave Green for information on the 7C images and flux density scale. We thank the staffs of GMRT, VLA and the Effelsberg telescope for their help with the observations. The GMRT is a national facility operated by the National Centre for Radio Astrophysics of the Tata Institute of Fundamental Research. The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under co-operative agreement by Associated Universities Inc. The Effelsberg 100-m telescope is operated by the MPIfR. This research has made use of NED which is operated by the Jet Propulsion Laboratory, Caltech, under contract with the National Aeronautics and Space Administration. We acknowledge use of the Digitized Sky Surveys which were produced at the Space Telescope Science Institute under US Government grant NAG W-2166. The images of these surveys are based on photographic data obtained using the Oschin Schmidt Telescope on Palomar Mountain and the UK Schmidt Telescope. We thank Matteo Murgia for access to the SYNAPE software and useful discussions. MJ was partly supported by the Polish State funds for scientific research in years 2005–2007 under contract no. 0425/PO3/2005/29. LS was supported by MEIN through the research project 1-P03D-003-29 during the years 2005–2008. This research was funded in part by NASA contract NAS8–36721, 487.
