ABSTRACT
We report the results of new Hubble Space Telescope imaging of the positions of six ultraluminous X-ray sources (ULXs). Using images in three Advanced Camera for Surveys (ACS) filters, we detect good candidate counterparts to four out of six ULXs, with one more possible detection, and observed magnitudes in the range \( m \sim 22–26 \) in the F606W filter. The extinction-corrected colours and absolute magnitudes vary from source to source, even after correcting for additional extinction in the host galaxy, and only one counterpart is readily explained as an OB star. Nevertheless, these counterparts are decent candidates for future follow-up in pursuit of dynamical mass constraints on the likely black holes powering these sources.

Key words: black hole physics – X-rays: binaries – X-rays: galaxies.

1 INTRODUCTION

The ongoing controversy regarding the true nature of the so-called ‘ultraluminous X-ray sources’ (ULXs) stems from the simple fact that their extraordinary observed X-ray luminosities, at \( >10^{39} \text{erg s}^{-1} \) in the 0.5–10 keV band alone, exceeds the Eddington limit for the stellar-mass black holes we observe in our own Galaxy. An obvious solution to this problem is that the black holes underlying ULXs are bigger, perhaps 2–3 orders of magnitude more massive [i.e. intermediate-mass black holes (IMBHs) with \( M_{\text{IMBH}} \sim 10^2–10^4 M_{\odot} \), e.g. Colbert & Mushotzky 1999]. The best supporting evidence for IMBHs derived from X-ray spectroscopy of luminous ULXs, that showed possible cool accretion disc spectral components, having temperatures consistent with discs around \( \sim 1000 M_{\odot} \) black holes (e.g. Miller, Fabian & Miller 2004). In some cases, this argument was supplemented by further evidence, for example the QPO detections from M82 X-1 (Strohmayer & Mushotzky 2003). However, there are strong arguments for the majority of ULXs possessing stellar-mass black holes, not least the high abundance of such objects in the most extreme star-forming environments (King 2004). Indeed, detailed re-evaluations of the X-ray spectra of ULXs have questioned whether the apparent cool accretion discs really do imply the presence of IMBHs (e.g. Goncalves & Soria 2006; Stobbart, Roberts & Wilms 2006). If ULXs do not contain the \( \sim 1000 M_{\odot} \) IMBHs suggested by cool discs, then the physical processes by which smaller black holes (stellar mass, or perhaps up to \( \sim 100 M_{\odot} \), cf. Stobbart et al. 2006) appear so luminous may include anisotropic radiation, relativistic beaming and/or truly super-Eddington emission (e.g. King et al. 2001; Begelman 2002; Körding, Falcke & Markoff 2002).

Multiwavelength follow-up – and, in particular, optical/ultraviolet (optical/UV) observations – can provide crucial diagnostics of the nature of ULXs. Probably the most important is the identification of an optical counterpart to the ULX. The study of such counterparts can reveal the type of the mass donor star, and subsequently lead to the single most important measurement for a ULX, namely constraining its mass function (and hence placing unambiguous limits on the black hole mass) by measuring a radial velocity curve. However, even initial identifications are not trivial in crowded galaxy fields at several Mpc distance. Fortunately, thanks to a combination of the sub-arcsec X-ray astrometry of Chandra and the very high spatial resolution and sensitivity in the optical/UV of the Hubble Space Telescope (HST), good identifications are now possible. Indeed, many recent studies have taken advantage of the excellent data from these missions to identify possible ULX counterparts (e.g. Goad et al. 2002; Liu, Bregman & Seitzer 2002, 2004; Kuntz et al. 2005; Soria et al. 2005; Ptak et al. 2006; Ramsey et al. 2006; Terashima, Inoue & Wilson 2006; Liu et al. 2007; Mucciarelli et al. 2007). Where such studies have focused on nearby (\( d < 10 \) Mpc) spiral galaxies, individual counterparts with magnitudes \( m_v \sim 22–26 \) and blue colours have frequently been found, consistent with the interpretation of ULXs as high-mass X-ray binaries, where the mass donor star is a giant (or supergiant) O4–B8 star filling its Roche lobe. However, an alternative possibility is that the blue colours are due to reprocessed emission from an X-ray-illuminated accretion disc (Kaaresen, Ward & Zezas 2004; Copperwheat et al. 2005; Rappaport, Podsiadelowski & Pfahl 2005). Indeed, Pakull, Grisé & Mottch (2006) argue that the blue counterpart to NGC 1313 X-2 is dominated by accretion disc light (although see
Table 1. Positions of the target ULXs as obtained from Chandra data, and the corresponding Galactic extinction.

Notes: aMagnitude of the counterpart at the pivot wavelength of the ACS filter. The uncertainty in the measurement is calculated by seeding the image with fake stars of the same magnitude. The two limits are calculated by seeding the images with fake stars covering a range of input magnitudes. bUBV magnitudes in the Vega magnitude system. These are extinction corrected for material in our own Galaxy, then directly photometered from the ACS filters as discussed in the text. cThe error includes an additional (relatively small) uncertainty from the calculated error in the slope of the power-law continuum used to photometer the data. We use a ν<sup>−1</sup> spectrum to provide the magnitude for the possible IC 342 X-2 counterpart, but quote no limits on non-detections as we cannot obtain a proxy for the spectral shape of this source from the one data point. dAbsolute magnitude of the counterpart at the distance of its host galaxy (also foreground extinction corrected). eUV magnitudes toward the ULX, external to our own Galaxy, measured by X-ray spectroscopy (see the text). fForeground extinction-corrected counterpart colours, again shown with a further possible extinction correction in parentheses.

Liu et al. (2007, for counter arguments). Optical spectroscopy shows a variation in the centroid of the He II λ4686 emission line from the disc, which might indicate that an IMBH is ruled out for this source, though further observations are required to distinguish whether this is a true radial velocity variation.

Here, we present the results of a programme to produce a deep, homogeneous set of imaging data for six nearby ULXs, designed to provide possible targets for future radial velocity studies. We selected ULXs from the ROSAT catalogues of Roberts & Warwick (2000) and Colbert & Ptak (2002) based on the following criteria: (i) distance d < 8 Mpc, to potentially resolve spatial scales below ∼2 pc using HST Advanced Camera for Surveys (ACS) data; (ii) the ULX is located away from the centre of the host galaxy, to avoid inherently dense stellar environments where individual identifications are unlikely and (iii) no ROSAT imaging data at the position of the ULXs existed at the time of sample selection. In addition, the selection of ROSAT ULXs (i.e. ULXs detected at relatively soft X-ray energies, < 2 keV) ensures a relatively low extinction in the host galaxies. The six target ULXs are listed in Tables 1 and 2, and we discuss the identification of optical counterparts to these objects in the following sections.

2 DATA REDUCTION

Our target ULXs were observed by HST between 2005 September and 2006 February (programme number 10579; see Table 2 for
New HST imaging of six ULX counterparts

3 IDENTIFICATION AND CHARACTERIZATION OF THE POSSIBLE NEW COUNTERPARTS

The key step in identifying optical counterparts to our target ULXs is registering the relative astrometries of the HST and Chandra data. Ideally, this would be done by finding a number of HST counterparts to Chandra X-ray sources; however, there were insufficient matches present in our data. Instead we aligned our ACS images to 2MASS and centroiding errors (using the WAVDETECT algorithm. We list the derived ULX positions and centroiding errors ($\sigma_{\text{cent}}$) in Table 1.

4 THE COUNTERPARTS

Our observations detect four likely counterparts to ULXs, plus two more possible. Three of these likely counterparts are previously unreported; the counterpart to IC 342 X-1 was reported twice before. It was described as ‘candidate 1’ of two possible counterparts by Grisé, Pakull & Motch (2006) based on ground-based imaging, and latterly identified as the unique counterpart ‘Star A’ in a separate HST programme by Feng & Kaaret (2008). Although their observations took place three months after ours, Feng & Kaaret’s Star A has identical $B$ and $V$ magnitudes to our detection (within the quoted errors), suggesting it displays little intrinsic variability. From their characterization of Star A, they derive a classification as an F8 to G0 Ib supergiant, although they choose to omit any corrections to their characterization based on extinction intrinsic to IC 342. Candidate 1 of Grisé et al. (2006) also displays a similar magnitude after extinction correction ($m_{V} \sim 22.3$).

The likely counterparts are all luminous point-like sources, with absolute magnitudes in the range $M_{V} \sim -3.4$ to $-7.6$, or perhaps even higher ($M_{V} \sim -5.1$ to $-9.3$) if we take into account possible additional extinction in the host galaxies of the ULXs. The inferred $U - B$ colours of these ULXs are very blue, in the range $-1.4$ to $-0.5$, or $-1.5$ to $-0.8$ accounting for the putative host galaxy reddening. The $B - V$ colour ranges from $-0.1$ to $0.6$ ($-0.6$ to $0.2$ with host galaxy reddening).

Of the two possible counterpart detections, IC 342 X-2 is very marginal, with a minimal detection in the F435W filter image alone.

These columns are approximations based on values taken from a range of models for the X-ray spectra of the ULXs. As the variance in measured columns between models can be factors of at least $\sim 2$, the uncertainties on the quoted values are large, though we note that this correction will always work in the sense of increasing the intrinsic brightness of the counterpart.

1 See http://cxc.harvard.edu/cal/ASPECT/fix_offset/

2 See http://cxc.harvard.edu/cal/ASPECT/celmore/
Figure 1. HST ACS images of ULX locations. North is up in each image. For each of the six targets, we show a wide-ACS/WFC F606W view of the ULX environment, with a true-colour blow-up of the immediate vicinity of the ULX beneath it (blue = F330W, green = F435W and red = F606W). The error circles are as per Table 1.
This is perhaps not surprising, given the high foreground Galactic extinction to IC 342, and the even higher X-ray column, which may result in >5 mag of extinction in the V band alone. In this regard, the detection in the F435W filter but not the F606W is very suspicious, and increases the chances of this being a spurious detection. M83 1XO 82, on the other hand, probably is a real detection. The question here is whether it is the correct one. It is suspiciously close (at ~5 arcsec distance) from the centre of a galaxy lying behind a spiral arm of M83, which does raise the question of whether this Chandra HRC data set has an unusually bad aspect solution, and the X-ray source is, in fact, located within the background galaxy (probably an active galactic nucleus). However, to argue against this, the colours of the counterpart are somewhat similar to IC 342 X-1, and (though it is fainter than IC 342 X-1 by ~2.5 mag) it is only ~1.5 mag intrinsically fainter than NGC 2403 X-1. Clearly, future work should attempt to clarify the astrometry for this field and confirm the likely nature of this X-ray source.

Previous observations have also revealed blue counterparts to ULXs, that have generally been identified as O or B stars. In order to clarify whether we are viewing similar objects, we referred to the work of Wegner (2006) to provide us with typical $M_V$ measurements for such stars, and Martins & Plez (2006) and Knyazeva & Kharitonov (1998) for typical colours. These colours for OB stars cover ranges of $U - B \sim -1.2 \rightarrow -0.6$ and $B - V \sim -0.3 \rightarrow -0.1$. Hence, taking only the Galactic extinction-corrected magnitudes into consideration, the four good candidate counterparts, in general, appear too red to be OB stars. This situation is, however, mostly remedied when we take into account possible extinction in the host galaxy – in most cases, the colours (particularly the $U - B$ colour) become sufficiently blue to originate in OB stars. However, the inherent uncertainty in this additional correction is large (see footnote 3), so it is perhaps sensible to simply conclude that the Galactic extinction-corrected magnitudes provide an upper (reddened) limit on the colours, which are intrinsically bluer than this value. Indeed, if some fraction of the additional X-ray absorption is local to the ULX accretion disc, or if the intense X-ray emission of the ULX can deplete the dust content of its local environment, it is quite plausible that the extinction to the optical counterpart within the host galaxy could be lower than estimated. Evidence supporting this is provided by Grisé et al. (2006), who infer $E(B - V) = 0.26$ within IC 342 from the Hα/Hβ ratio (albeit from the bubble nebula surrounding this ULX) – this is somewhat smaller than the value $E(B - V) = 0.53$ within IC 342 derived from the X-ray absorption.

Supposing that the true counterpart colours lie between the tabulated colours and magnitudes, (i.e. with and without additional host galaxy extinction), we can speculate on the nature of the counterparts. The colours and magnitude of the counterpart to NGC 2403 X-1 suggest it could plausibly be an O star or an early B giant/B supergiant. NGC 4485 X-1 is somewhat trickier to classify – it is relatively blue in $B - V$ but red in $U - B$ compared to other candidates. Given its high absolute magnitude perhaps the most likely explanation is that this object is a young, compact stellar cluster that has lost its youngest and hottest OB stars (perhaps similar to HST-1 identified by Goad et al. 2002, a possible counterpart to NGC 5204 X-1, though this was later ruled out by Liu et al. 2004). The counterpart to NGC 5055 X-2 is an oddball – its absolute magnitude is bright enough for an OB giant/supergiant, but its $U - B$ colour is too blue, whereas its $B - V$ colour is too red. It is unclear what is causing this unusual colour, though domination of the optical light by the accretion disc can be ruled out, as this will produce a spectrum redder than an O star. We speculate that this blueess could be caused by emission lines and/or non-stellar processes, and may possibly even be attributable to variability in the accretion disc. However, this cannot be confirmed without repeated spectroscopic observations. Finally, the $B - V$ colour of the counterpart to IC 342 X-1 is quite red, even after correction, apparently ruling out an OB star unless substantial additional local extinction (not seen in X-rays) is present. In fact, its red colour and magnitude are more reminiscent of a F-type supergiant, probably earlier in type (F0–F5 supergiant) than suggested in Feng & Kaaret (2008) after accounting for the additional column within IC 342. Again, this source would benefit from further deep spectroscopic follow-up to clarify its nature.

Unlike previous studies, it appears that few of our counterparts can be easily associated with individual OB stars. This may be a result of detecting fainter targets than previously observed (and hence poorer data quality), a situation that could be improved with future, deeper observations. Indeed, a combination of deeper observations and the new generation of models for the optical emission of ULXs, such as those of Copperwheat et al. (2007), Patruno & Zampieri (2008) and Madhusudhan et al. (2008), should reveal more of the nature of ULXs. So far, the work of both Copperwheat et al. and Patruno & Zampieri has suggested that the currently known counterparts of ULXs are older and less massive than initially suggested (due to the modifying effects of, for example, the illumination of the donor star by the ULX on the optical emission of these systems). All authors agree that the presence of an IMBH will increase the optical luminosity of the systems, and indeed Madhusudhan et al. claim that the colours of current ULX counterparts appear more consistent with their models incorporating the presence of an IMBH.

However, the most important observations remain those that could constrain the mass of a ULX dynamically. Rather encouragingly, recent work by Orosz et al. (2007), Prestwich et al. (2007) and Silverman & Filippenko (2008) shows that this can be done for massive stellar donors in X-ray binary systems out to distances ~1 Mpc. To perform similar observations – particularly based on the Hβ $\lambda$ 4686 line used by Prestwich et al. (2007) and Silverman & Filippenko (2008) – on the slightly more distant ULX counterparts may therefore only be a small step away. The counterparts revealed by this study are promising candidates for such observations, albeit technically challenging ones for the immediate future due to their relatively faint magnitudes. Such studies should be pursued regardless, as the prize – a dynamical mass constraint on the black hole in an ULX – is the single most important measurement to be made in this field.

**ACKNOWLEDGMENTS**

The authors thank the referee (Manfred Pakull) for comments that have substantially improved this paper. We also gratefully acknowledge PPARC for financial support during the early stages of this work. Based on observations made with the NASA/ESA Hubble Space Telescope, obtained at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. These observations are associated with program 10579.
