We claim and present arguments to the effect that a large class of manifold learning algorithms that are essentially local and can be framed as kernel learning algorithms will suffer from the curse of dimensionality, at the dimension of the true underlying manifold. This observation invites an exploration of nonlocal manifold learning algorithms that attempt to discover shared structure in the tangent planes at different positions. A training criterion for such an algorithm is proposed, and experiments estimating a tangent plane prediction function are presented, showing its advantages with respect to local manifold learning algorithms: it is able to generalize very far from training data (on learning handwritten character image rotations), where local nonparametric methods fail.

1 Introduction ---

A central issue in order to obtain generalization is how information from training examples is used to make predictions about new examples. In nonparametric models, there are no strong prior assumptions about the structure of the underlying generating distribution, and this might make it difficult to generalize far from the training examples, as illustrated by the curse of dimensionality. In recent years, there has been a lot of work on unsupervised learning based on characterizing a possibly nonlinear manifold near which the data would lie, such as locally linear embedding (LLE) (Roweis & Saul, 2000), Isomap (Tenenbaum, de Silva, & Langford, 2000), kernel principal component analysis (or kernel PCA) (Schölkopf, Smola, & Müller, 1998), Laplacian eigenmaps (Belkin & Niyogi, 2003), and manifold charting (Brand, 2003). These are all essentially nonparametric methods that can be shown to be kernel methods with an adaptive kernel (Bengio et al., 2004) and represent the manifold on the basis of local neighborhood relations. Very often, these relations are constructed using the nearest neighbors graph (the graph with one vertex per observed example and arcs

between near neighbors). These methods characterize the manifold through an embedding that associates each training example (an input object) with a low-dimensional coordinate vector (the coordinates on the manifold). Other closely related methods characterize the manifold as well as noise around it. Most of these methods consider the density as a mixture of flattened gaussians, such as mixtures of factor analyzers (Ghahramani & Hinton, 1996), manifold Parzen windows (Vincent & Bengio, 2003), and other local PCA models such as mixtures of probabilistic PCA (Tipping & Bishop, 1999). This is not an exhaustive list, and recent work also combines models through a mixture density and dimensionality reduction (Teh & Roweis, 2003; Brand, 2003).

In this letter, we claim that there is a fundamental weakness with such nonparametric kernel methods, due to the locality of learning. We show that for these methods, the definition of the local tangent plane of the manifold at a point x is defined based mostly on the near neighbors of x . As a consequence, it is difficult with such methods to generalize to new combinations of values x that are far from the training examples x_i , where being “far” is a notion that should be understood in the context of several factors: the amount of noise around the manifold (the examples do not lie exactly on the manifold), the curvature of the manifold, and the dimensionality of the manifold. For example, if the manifold curves quickly around x , neighbors need to be closer for a locally linear approximation to be meaningful. Dimensionality of the manifold compounds that problem because the number of data thus needed will grow exponentially with it. Saying that y is “far” from x means that y is not well represented by its projection on the tangent plane at x . In this letter, we explore one way to address these problems, based on estimating the tangent planes of the manifolds as a function F taking x as argument and computing a prediction of the tangent plane around x . The important point is that F can be estimated not only from the data around x but from the whole dataset. Hence if there is a compact way to represent the manifold structure and if the class from which F is chosen can represent it and if F can be optimized to learn it, then it can generalize to regions with not enough data to determine the manifold shape from looking at near neighbors (which may be the case even in regions where there is data, when the manifold dimension is high, or the manifold is highly curved, or the data do not lie strictly on the manifold). We present experiments on a variety of tasks illustrating the weaknesses of the local manifold learning algorithms. The most striking result is that the nonlocal model is able to generalize a notion of rotation learned on one kind of image (digits) to a very different kind (alphabet characters), very far from the training data.

2 Local Manifold Learning

By *local manifold learning*, we mean a method that derives information about the local structure of the manifold (i.e., implicitly its tangent directions)

at x based mostly on the training examples around x . There is a large group of manifold learning methods (as well as spectral clustering methods) that share several characteristics and can be seen as data-dependent kernel PCA (Bengio et al., 2004). These include LLE (Roweis & Saul, 2000), Isomap (Tenenbaum et al., 2000), kernel PCA (Schölkopf et al., 1998), and Laplacian eigenmaps (Belkin & Niyogi, 2003). The methods first build a data-dependent gram matrix M with $n \times n$ entries $K_D(x_i, x_j)$ where $D = \{x_1, \dots, x_n\}$ is the training set and K_D is a data-dependent kernel, and compute the eigenvector-eigenvalue pairs $\{(v_k, \lambda_k)\}$ of M . The embedding of the training set is obtained directly from the principal eigenvectors v_k of M (the i th element of v_k gives the k th coordinate of x_i 's embedding, i.e., $e_k(x_i) = v_{ki}$, possibly scaled by $\sqrt{\frac{\lambda_k}{n}}$), and the embedding for a new example can be estimated using the Nyström formula (Bengio et al., 2004),

$$e_k(x) = \frac{1}{\lambda_k} \sum_{i=1}^n v_{ki} K_D(x, x_i), \tag{2.1}$$

for the k th coordinate of x , where λ_k is the k th eigenvalue of M (the optional scaling by $\sqrt{\frac{\lambda_k}{n}}$ would also apply). Equation 2.1 says that the embedding for a new example x is a local interpolation of the manifold coordinates v_{ki} of its neighbors x_i , with interpolating weights given by $\frac{K_D(x, x_i)}{\lambda_k}$. To see more clearly how the tangent plane may depend only on the neighbors of x , consider the relation between the tangent plane and the embedding function: for any K_D the tangent plane at x is simply the subspace spanned by the vectors $\frac{\partial e_k(x)}{\partial x}$, as illustrated in Figure 1. We show below that in the case of very local kernels like that of LLE, spectral clustering with gaussian kernel, Laplacian eigenmaps, or kernel PCA with gaussian kernel, $\frac{\partial e_k(x)}{\partial x}$ depends significantly only on the near neighbors of x . Consider first the simplest case: kernel PCA with a gaussian kernel. Then $\frac{\partial e_k(x)}{\partial x}$ can be closely approximated by a linear combination of the difference vectors $(x - x_j)$ for x_j near x . The weights of that combination may depend on the whole data set, but if the ambient space has many more dimensions than the number of such near neighbors of x , this is a very strong, locally determined constraint on the shape of the manifold. If there are enough examples in a small enough neighborhood around x then these approaches work well. However, if the dimensionality, curvature and noise are too large, generalization will be poor, as argued in more detail in the next subsection.

Let us now consider the case of LLE and show that similar results are obtained. A kernel consistent with LLE is $K_{LLE}(x, x_i)$ being the weight of x_i in the reconstruction of x by its k nearest neighbors (Bengio et al., 2004). This weight is obtained by the following equation (Saul & Roweis, 2002),

$$K_{LLE}(x, x_i) = \frac{\sum_{j=1}^k G_{ij}^{-1}}{\sum_{l=1}^k \sum_{m=1}^k G_{lm}^{-1}} \tag{2.2}$$

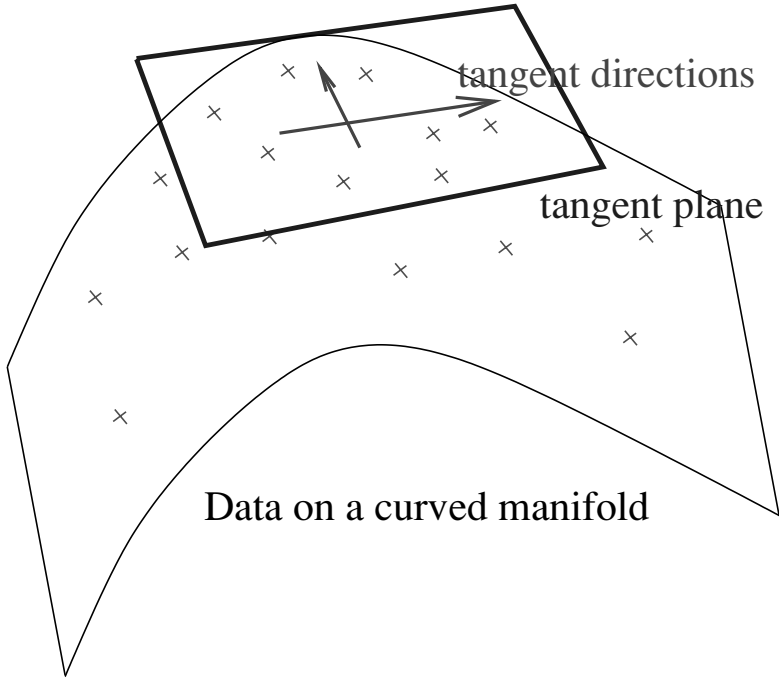

Figure 1: The tangent plane is spanned by the vectors $\frac{\partial e_k(x)}{\partial x}$, that is, the directions of most rapid change of coordinate k when moving along the manifold.

with G^{-1} the inverse of the local gram matrix G ,

$$G_{lm} = (x - x_l) \cdot (x - x_m),$$

for all pairs (x_l, x_m) of k nearest neighbors of x in the training set. Because $G^{-1} = |G|^{-1}C^T$ with C the cofactor matrix of G , and because $|G|^{-1}$ at the numerator and the denominator cancel, equation 2.2 can be rewritten as

$$K_{LLE}(x, x_i) = \frac{\sum_j s_j \prod_{l,m} (G_{lm})^{t_{jm}}}{\sum_j u_j \prod_{l,m} (G_{lm})^{v_{jm}}},$$

where $\sum_j s_j \prod_{l,m} (G_{lm})^{t_{jm}}$ is a polynomial expansion of the cofactor element C_{ij} (i.e. a determinant), and similarly for C_{lm} . Consequently, thanks to the usual derivation rules, its derivative is a linear combination of derivatives

of terms of the form $(G_{lm})^t$. But

$$\begin{aligned} \frac{\partial(G_{lm})^t}{\partial x} &= \frac{\partial((x - x_l) \cdot (x - x_m))^t}{\partial x} \\ &= t(G_{lm})^{t-1}(x - x_l + x - x_m), \end{aligned}$$

which implies that the derivative of $K_{LLE}(x, x_i)$ with regard to x is in the span of the vectors $(x - x_j)$ with x_j one of the k nearest neighbors of x .

The case of Isomap is less intuitively obvious, but we show below that it is also local. Let $\mathcal{D}(a, b)$ denote the graph geodesic distance going only through a, b , and points from the training set. As shown in Bengio et al. (2004), the corresponding data-dependent kernel can be defined as

$$K_D(x, x_i) = -\frac{1}{2}(\mathcal{D}(x, x_i)^2 - \frac{1}{n} \sum_j \mathcal{D}(x, x_j)^2 - \bar{\mathcal{D}}_i + \bar{\mathcal{D}}),$$

where

$$\bar{\mathcal{D}}_i = \frac{1}{n} \sum_j \mathcal{D}(x_i, x_j)^2$$

and

$$\bar{\mathcal{D}} = \frac{1}{n} \sum_j \bar{\mathcal{D}}_j.$$

Let $\mathcal{N}(x, x_i)$ denote the index j of the training set example x_j that is the neighbor of x minimizing $\|x - x_j\| + \mathcal{D}(x_j, x_i)$. Then

$$\begin{aligned} \frac{\partial e_k(x)}{\partial x} &= \frac{1}{\lambda_k} \sum_i v_{ki} \left(\frac{1}{n} \sum_j \mathcal{D}(x, x_j) \frac{(x - x_{\mathcal{N}(x, x_j)})}{\|x - x_{\mathcal{N}(x, x_j)}\|} \right. \\ &\quad \left. - \mathcal{D}(x, x_i) \frac{(x - x_{\mathcal{N}(x, x_i)})}{\|x - x_{\mathcal{N}(x, x_i)}\|} \right), \end{aligned} \tag{2.3}$$

which is a linear combination of vectors $(x - x_k)$, where x_k is a neighbor of x . This clearly shows that the tangent plane at x associated with Isomap is also included in the subspace spanned by the vectors $(x - x_k)$ where x_k is a neighbor of x .

There is also a variety of local manifold learning algorithms that can be classified as “mixtures of pancakes” (Ghahramani & Hinton, 1996; Tipping & Bishop, 1999; Vincent & Bengio, 2003; Teh & Roweis, 2003; Brand,

2003). These are generally mixtures of gaussians with a particular covariance structure. When the covariance matrix is approximated using its principal eigenvectors, this leads to “local PCA” types of methods. For these methods, the local tangent directions directly correspond to the principal eigenvectors of the local covariance matrices. Learning is also local since it is mostly the examples around the gaussian center that determine its covariance matrix. The problem is not so much due to the form of the density as a mixture of gaussians. The problem is that the local parameters (e.g., local principal directions) are estimated mostly based on local data. There is usually a nonlocal interaction between the different gaussians, but its role is mainly of global coordination, for example, where to set the gaussian centers to allocate them properly where there are data and optionally how to orient the principal directions so as to obtain a globally coherent coordinate system for embedding the data.

2.1 Where Local Manifold Learning Would Fail. It is easy to imagine at least four causes of failure for local manifold learning methods, which can be compounded:

- **Noise around the manifold.** Data are not exactly lying on the manifold. In the case of nonlinear manifolds, the presence of noise means that more data around each pancake region will be needed to properly estimate the tangent directions of the manifold in that region. More data are needed simply to average out the noise sufficiently (some random directions quite different from the local principal directions might otherwise be selected).
- **High curvature of the manifold.** Local manifold learning methods basically approximate the manifold by the union of many locally linear patches. For this to work, there must be at least d (with $d =$ manifold dimension) close enough examples in each patch (more with noise). With a high curvature manifold, more—smaller—patches will be needed, and the number of patches required to cover the manifold will grow exponentially with the dimensionality of the manifold. Consider, for example, the manifold of translations of a high-contrast image (see Figure 2). The tangent direction corresponds to the change in image due to a small translation; it is nonzero only at the edges in the image. After a 1 pixel translation, the edges have moved by 1 pixel and may not overlap much with the edges of the original image if it had high contrast. This is indeed a very high curvature manifold. In addition, if the image resolution is increased, then many more training images will be needed to capture the curvature around the translation manifold with locally linear patches. Yet the physical phenomenon responsible for translation is expressed by a simple equation, which does not get more complicated with increasing resolution.

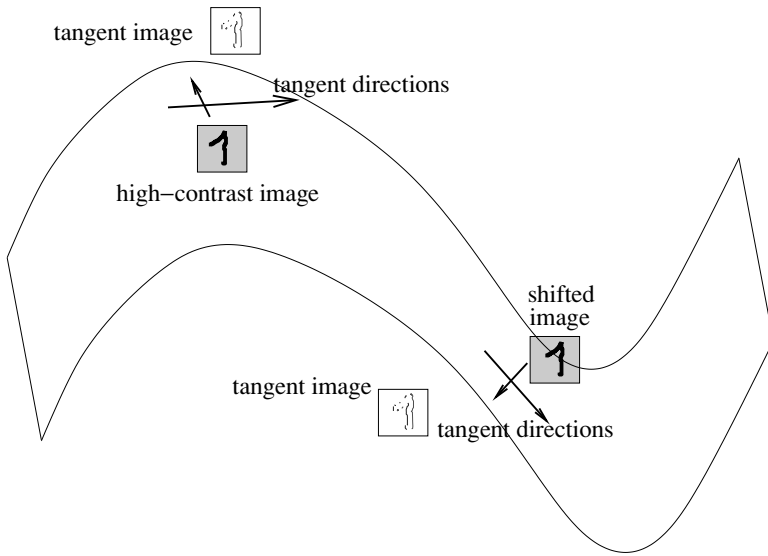

Figure 2: The manifold of translations of a high-contrast image has very high curvature. A smooth manifold is obtained by considering that an image is a sample on a discrete grid of an intensity function over a two-dimensional space. The tangent vector for translation is thus a **tangent image**, and it has high values only on the digit edges. The tangent plane for an image translated by only 1 pixel looks similar but changes abruptly since the edges are also shifted by 1 pixel. Hence the two tangent planes are almost orthogonal.

- **High intrinsic dimension of the manifold.** We have already seen that high manifold dimensionality d is hurtful because $O(d)$ examples are required in each patch and $O(r^d)$ patches (for some r depending on curvature) are necessary to span the manifold.
- **Presence of many manifolds with few data per manifold.** In many real-world settings, there is not just one global manifold but a large number of (generally nonintersecting) manifolds, which, however, share something about their structure. A simple example is the manifold of transformations (e.g., viewpoint, position, lighting) of 3D objects in 2D images. There is one manifold per object instance (corresponding to the successive application of small amounts of all of these transformations). If there are only a few examples for each such class, then it is almost impossible to learn the manifold structures using only local manifold learning.

However, if the manifold structures are generated by a common underlying phenomenon, then a nonlocal manifold learning method could potentially learn all of these manifolds and even generalize to

manifolds for which a single instance is observed, as demonstrated in the experiments in section 5.

3 Nonlocal Manifold Tangent Learning

We propose here a new non-local manifold learning methodology. We choose to characterize the manifolds in the data distribution through a matrix-valued function $F(x)$ that predicts at $x \in \mathbf{R}^m$ a basis for the tangent plane of the manifold near x —hence, $F(x) \in \mathbf{R}^{d \times m}$ for a d -dimensional manifold. Basically, $F(x)$ specifies in which directions (with regard to x) one expects to find near neighbors of x .

We are going to consider a simple supervised learning setting to train this function. As with Isomap, we consider that the vectors $(x - x_i)$ with x_i a near neighbor of x span a noisy estimate of the manifold tangent space. We propose to use them to define a “noisy target” for training $F(x)$. In our experiments, we simply collected the k nearest neighbors of each example x , but better selection criteria might be devised. Points on the predicted tangent subspace can be written $x + F(x)'w$, with $w \in \mathbf{R}^d$ being local coordinates in the basis specified by $F(x)$. Several criteria are possible to match the neighbor’s differences with the subspace defined by $F(x)$. One that yields to simple analytic calculations is to minimize the distance between the $x - x_j$ vectors and their projection on the subspace defined by $F(x)$. The low-dimensional local coordinate vector $w_{tj} \in \mathbf{R}^d$ that matches neighbor x_j of example x_t is thus an extra free parameter that has to be optimized, but this optimization can be done analytically. The overall training criterion involves a double optimization over function F and local coordinates w_{tj} of what we call the relative projection error,

$$R(F, w) = \sum_t \sum_{j \in \mathcal{N}(x_t)} \frac{\|F(x_t)'w_{tj} - (x_t - x_j)\|^2}{\|x_t - x_j\|^2}, \quad (3.1)$$

where $w = w_{tj}$ and $\mathcal{N}(x)$ denotes the selected set of near neighbors of x . The objective is to minimize R across F and w simultaneously. The normalization by $\|x_t - x_j\|^2$ is to avoid giving more weight to the neighbors that are farther away. The above ratio amounts to minimizing the square of the sinus of the projection angle. To perform the above minimization, we can do coordinate descent (which guarantees convergence to a minimum), that is, alternate changes in F and changes in w that at each step go down the total criterion. Since the minimization over w can be done separately for each example x_t and neighbor x_j , it is equivalent to minimize

$$\frac{\|F(x_t)'w_{tj} - (x_t - x_j)\|^2}{\|x_t - x_j\|^2} \quad (3.2)$$

over vector w_{ij} for each such pair (done analytically) and compute the gradient of the above over F (or its parameters) to move F slightly (in the experiments we used stochastic gradient on the parameters of F). The solution for w_{ij} is obtained by solving the linear system

$$F(x_t)F(x_t)'w_{ij} = F(x_t)\frac{(x_t - x_j)}{\|x_t - x_j\|^2}. \tag{3.3}$$

In our implementation, this is done robustly through a singular value decomposition,

$$F(x_t)' = USV'$$

and, introducing a matrix B

$$w_{ij} = B(x_t - x_j),$$

where B can be precomputed for all the neighbors of x_t ,

$$B = \left(\sum_{k=1}^d 1_{S_k > \epsilon} V_k V_k' / S_k^2 \right) F(x_t),$$

with ϵ a small regularization threshold. The gradient of the criterion with respect to the i th row of $F(x_t)$, holding the local coordinates w_{ij} fixed, is simply

$$\frac{\partial R}{\partial F_i(x_t)} = 2 \sum_{j \in \mathcal{N}(x_t)} \frac{w_{ij}}{\|x_t - x_j\|} (F(x_t)'w_{ij} - (x_t - x_j)), \tag{3.4}$$

where w_{ij} is the i th element of w_{ij} . In practice, it is not necessary to store more than one w_{ij} vector at a time. In the experiments, $F(\cdot)$ is parameterized as standard one-hidden-layer neural network with m inputs and $d \times m$ outputs. It is trained by stochastic gradient descent, one example x_t at a time. The rows of $F(x_t)$ are not constrained to be orthogonal or to have norm 1. They are used only to define a basis for the tangent plane.

Although the above algorithm provides a characterization of the manifold, it does not directly provide an embedding or a density function. However, once the tangent plane function is trained, there are ways to use it to obtain all of the above. The simplest method is to apply existing algorithms that provide both an embedding and a density function based on a gaussian mixture with pancake-like covariances. For example one could use charting (Brand, 2003), and the local covariance matrix around x could

be of the form $F(x)^T F(x) + \sigma^2 I$, i.e. F specifies both the principal directions and variances in these directions, and σ^2 takes care of off-manifold noise.

Figure 3 illustrates why nonlocal tangent learning can be a more accurate predictor of the tangent plane. Since the tangent plane is estimated by a smooth predictor (in our case, a neural net) that has the potential to generalize nonlocally, the tangent plane tends to vary smoothly between training points. This will not be true for local PCA, for example, especially if there are not many training points. Note that this type of estimator can make predictions anywhere in the data space, even far from the training examples, which can be problematic for algorithms such as local PCA.

4 Previous Work on Manifold Learning

The nonlocal manifold learning algorithm presented here (find $F(\cdot)$, which minimizes $\min_w R(F, w)$, is similar to the one proposed in Rao and Ruderman (1999) to estimate the generator matrix of a Lie group. That group defines a one-dimensional manifold generated by following the orbit $x(t) = e^{Gt} x(0)$, where G is an $m \times m$ matrix and t is a scalar manifold coordinate. A multidimensional manifold can be obtained by replacing Gt above by a linear combination of multiple generating matrices. In Rao and Ruderman (1999) the matrix exponential is approximated to first order by $(I + Gt)$, and the authors estimate G for a simple signal undergoing translations, using as a criterion the minimization of $\sum_{x, \tilde{x}} \min_t \|(I + Gt)x - \tilde{x}\|^2$, where \tilde{x} is a neighbor of x in the data. Note that in this model, the tangent plane is a linear function of x , that is, $F(x) = Gx$. By minimizing the above across many pairs of examples, a good estimate of G for the artificial data was recovered by Rao and Ruderman (1999). Our proposal extends this approach to multiple dimensions and nonlinear relations between x and the tangent planes.

The work on tangent distance (Simard, LeCun, & Denker, 1993), though more focused on character recognition, also uses information from the tangent plane of the data manifold. In Simard et al., the tangent planes are used to build a nearest-neighbor classifier that is based on the distance between the tangent subspaces around two examples to be compared. The tangent vectors that span the tangent space are not learned, but rather are obtained analytically a priori for transformations that locally do not change the class label, such as rotation, location shift, and thickness change. Hastie, Simard, and Sackinger (1995) and Hastie and Simard (1998) present a tangent subspace learning algorithm to learn character prototypes along with a tangent plane around each prototype, which reduces the time and memory requirements of the nearest-neighbor tangent distance classifier. Unlike in the case of Rao and Ruderman (1999), the manifold can be more than one-dimensional (they present results for 12 dimensions), but the manifold

Figure 3: The difference between local PCA and nonlocal tangent learning. (Top) What the one-dimensional tangent plane learned by local PCA (using two nearest neighbors) might look like for the three data points. (Bottom) The same but for nonlocal tangent learning. We emphasize here that with nonlocal tangent learning, the predicted tangent plane should change smoothly between points, and new predictions can be made anywhere in the data space.

is locally linear around each prototype (hence, must be globally smooth if the number of prototypes is significantly fewer than the number of examples). This learning procedure exploits the a priori tangent vector basis for the training points, which is computed analytically as in tangent distance (Simard et al., 1993). Nonlocal tangent learning can be viewed as an extension of these ideas that avoids the need for explicit prior knowledge on

the invariances of objects in each class and also introduces the notion of nonlocal learning of the manifold structure.

More generally, we can say that nonlocal tangent learning, local PCA, LLE, Isomap, and tangent subspace learning all try to learn a manifold structure (either the embedding or the tangent plane) that respects local metric structure. Since all of them implicitly or explicitly estimate the tangent plane, they all have the potential to learn invariants that could be useful for transformation-invariant classification. Local PCA and LLE are based on the Euclidean metric Isomap on an approximate geodesic metric, and Hastie et al. (1995) use the tangent distance metric based on a priori knowledge about the domain. One important difference with the ideas presented here is that for all these algorithms, the predicted manifold structure at x is obtained essentially using only local information in the neighborhood of x . We believe that the main conceptual advantage of the approach proposed here over local manifold learning is that the parameters of the tangent plane predictor can be estimated using data from very different regions of space, thus in principle allowing it to be less sensitive to all four of the problems described in section 2.1, thanks to sharing of information across these different regions.

5 Experimental Results

The objective of the experiments is to validate the proposed algorithm: Does it provide a good estimate of the true tangent planes? Does it generalize better than a local manifold learning algorithm, especially in regions “far” from the data?

5.1 Error Measurement. In addition to visualizing the results for the low-dimensional data, we measure performance by considering how well the algorithm learns the local tangent distance, as measured by the normalized projection error of nearest neighbors (see equation 3.2). We compare the errors of four algorithms, always on test data not used to estimate the tangent plane: (1) true analytic (using the true manifold’s tangent plane at x computed analytically), (2) tangent learning (using the neural network tangent plane predictor $F(x)$, trained using the $k \geq d$ nearest neighbors in the training set of each training set example), (3) Isomap (using the tangent plane defined in equation 2.3), or (4) local PCA (using the d principal components of the empirical covariance of the k nearest neighbors of x in the training set).

5.2 Tasks

5.2.1 Multiple Sinusoidal Manifolds. We first consider a low-dimensional but multimanifold problem. The data $\{x_i\}$ are in two dimensions and coming from a set of 40 1D manifolds. Each manifold is composed of four near points

Figure 4: Multiple Sinusoidal Manifolds. Two-dimensional data with 1D sinusoidal manifolds; the method indeed captures the tangent planes. The small segments are the estimated tangent planes. Small dots are the training examples.

obtained randomly from a sinus curve, that is, $\forall i \in 1..4$,

$$x_i = (a + t_i, \sin(a + t_i) + b),$$

where a , b , and t_i are randomly chosen. Four neighbors were used for training both the nonlocal tangent learning algorithm and the benchmark local nonparametric estimator (local PCA of the four neighbors). Figure 4 shows the training set and the tangent planes recovered with nonlocal tangent learning, both at training examples and generalizing away from the data. The neural network has 10 (chosen arbitrarily) hidden units. This problem is particularly difficult for local manifold learning: the out-of-sample relative projection errors are, respectively, 0.09 for the true analytic plane, 0.25 for nonlocal tangent learning, and 0.81 for local PCA.

5.2.2 Gaussian Curves in a High-Dimensional Space. This is a higher-dimensional manifold learning problem, with 41 dimensions. The data are generated by sampling gaussian curves. Each curve is of the form $x(i) = e^{t_i - (-2+i/10)^2/b_2}$ with $i \in \{0, 1, \dots, 40\}$. Note that the tangent vectors

Figure 5: Gaussian Curves in a High-Dimensional Space. Relative projection error for k th nearest neighbor with regard to k , for compared methods (from lowest to highest at $k = 1$: analytic, tangent learning, local PCA, Isomap). Note the U shape due to opposing effects of curvature and noise.

are not linear in x . The manifold coordinates are t_1 and t_2 , sampled uniformly, respectively, from $(-1, 1)$ and $(0.1, 3.1)$. Normal noise (standard deviation = 0.001) is added to each point. One hundred example curves were generated for training and 200 for testing. The neural network has 100 hidden units. Figure 5 shows the relative projection error as a function of the number of nearest neighbors, for the four methods on this task. First, the error decreases because of the effect of noise (nearby noisy neighbors may form a high angle with the tangent plane). Then it increases because of the manifold curvature (farther-away neighbors form a larger angle). This effect is illustrated schematically in Figure 6 and gives rise to the U-shaped projection error curve in Figure 5.

5.2.3 Rotation Manifold. This is a high-dimensional multimanifold task, involving digit images to which we have applied slight rotations in such a way as to have the knowledge of the analytic formulation of the manifolds. There is one rotation manifold for each instance of digit from the database, but only two examples for each manifold: one real image from the MNIST data set and one slightly rotated image. There are 1000×2 examples used

Figure 6: Schematic explanation of the U-shaped curve in projection error. With noise around the manifold, nearest examples tend to have a large angle, but because of curvature, the error also increases with distance to the reference point.

for training and 1000×2 for testing. In this context we use $k = 1$ nearest neighbor only, and the manifold dimension is 1. The average relative projection error for the nearest neighbor is 0.27 for the analytic tangent plane (obtained using the same technique as in Simard et al. (1993)), 0.43 with tangent learning (100 hidden units), and 1.5 with local PCA. Note the neural network would probably overfit if trained too much (here, only 100 epochs).

An even more interesting experiment consists of applying the above-trained predictor on novel images that come from a very different distribution but that shares the same manifold structure. It was applied to images of other characters that are not digits. We have used the predicted tangent planes to follow the manifold by small steps (this is very easy to do in the case of a 1D manifold). More formally, this corresponds to the following pseudocode:

WalkOnManifold($x, F(\cdot), i, nsteps, stepsize$) for s from 1 to $nsteps$

1. $d_s = SVD(F(x), i)$
2. $x = x + d_s \cdot stepsize$

Here, x is the initial image, $F(\cdot)$ is the tangent predictor, $nsteps$ is the number of steps, $stepsize$ controls how far in the direction d_s each step is made, and $SVD(F(x), i)$ is a function that returns the i th orthogonal basis vector of the subspace spanned by the rows of $F(x)$ using its SVD decomposition. Note that the sign of $stepsize$ also determines the orientation of the walk. Also,

Figure 7: Rotational Manifold. (Left) Original image. (Middle) Applying a small amount of the predicted rotation. (Right) Applying a larger amount of the predicted rotation. (Top) Using the estimated tangent plane predictor. (Bottom) Using local PCA, which is clearly much worse (the letter is not rotated).

since in this task, the dimension of the manifold is only 1, then we have $i = 1$ and the SVD is not necessary. We have considered the more general case only because it will be used in the next task.

Figure 7 shows the effect of applying WalkOnManifold on a letter M image for a few and a larger number of steps, for both the neural network predictor and the local PCA predictor. This example illustrates the crucial point that nonlocal tangent plane learning is able to generalize to truly novel cases, where local manifold learning fails. The results showed in Figure 7 provide evidence of the impressive extrapolation capacity of nonlocal tangent learning, since the M letter is quite different from any digit in the training set; the neural network is not just locally smoothing the tangent plane estimation, but it truly generalizes the notion of rotation (here) to new objects.

Since this experiment was set so that the only class-invariant transformation that could be learned would be the rotation transformation, one might wonder in what ways this task differs from supervised learning, that is, predicting the effect of a slight rotation on an image. First, one should note that we are predicting an undirected vector (i.e., rotations one way or the other are both acceptable), and second, the procedure can be readily generalized to predicting a whole tangent plane, without prior knowledge about invariants of the inputs, as shown with the next set of experiments, in which only natural data are used to infer the shape of the manifold.

Figure 8: Digit Images Manifold. Examples of the “walk on the manifold” for USPS digit samples (middle row). There is one model per digit class (column). Moving up or down the column corresponds to moving along one of the learned directions. Only the middle row corresponds to an actual example image; the other rows are obtained by walking one way or the other along the manifold.

5.2.4 Digit Images Manifold. Finally, we performed the following experiment in order to observe the invariances that can be learned with nonlocal tangent learning for a typical character recognition data set. These invariances can be compared with those reported for other methods, such as in Hastie et al. (1995). We used the first 6291 examples from the U.S. Postal Service (USPS) training set to train a separate neural network per each digit class, using nonlocal tangent learning. For this experiment, the hyperparameters (number of neighbors, number of hidden units, number of training epochs through early stopping) were tuned using a validation set (the 1000 USPS examples following the training set), with normalized projection error. The manifold dimension was chosen to be 7, following inspiration from the tangent distance work (Simard et al., 1993). For each class, we chose one digit example and performed a walk on the manifold as indicated by the pseudocode of WalkOnManifold for the rotation manifold task in order to visualize the learned manifold around the example image.

The results are plotted in Figure 8. The values of $nsteps$ and i were tuned manually to clarify visually the effect of the learned transformations. Note that those transformations are not linear, since the directions d_i are likely to be different from one step to another, and visual inspection also suggests so (e.g., changing the shape of the loop in a 2).

The overall picture is rather good, and some of the digit transformations are quite impressive, showing that the model learned typical transformations. For instance, we can see that nonlocal tangent learning was able to rotate the digit ‘8’ so that it would stand straight. In our opinion, those

transformations compare well to those reported in Hastie et al. (1995), although no prior knowledge about images was used here in order to obtain these transformations.

In Bengio and Larochelle (2006), we describe an extension of nonlocal tangent learning: nonlocal manifold Parzen, which uses nonlocal learning to train a manifold Parzen (Vincent & Bengio, 2003) density estimator. The basic idea is to estimate not only the tangent plane but also variances in each of the local principal directions, as functions of x . Having both principal directions and variances, one can write down a locally gaussian density and estimate the global density as a mixture of these gaussian components (one on each training example). From the density, one can readily obtain a classifier using one density estimator per class. Improvements with respect to local learning algorithms on the out-of-sample likelihood and classification error are reported for toy and real problems, such as the USPS digit recognition task. Note that this extension provides other ways to do model selection (e.g., by cross validation on the out-of-sample likelihood or classification error).

6 Conclusion

The central claim of this letter is that there are fundamental problems with local nonparametric approaches to manifold learning, essentially due to the curse of dimensionality (at the dimensionality of the manifold), but worsened by manifold curvature, noise, and the presence of several disjoint manifolds. To address these problems, we propose that learning algorithms should be designed in such a way that they can share information, coming from different regions of space, about the structure of the manifold. In this spirit, we have proposed a simple learning algorithm based on predicting the tangent plane at x with a function $F(x)$ whose parameters are estimated using the whole data set. Note that the same fundamental problems are present with nonparametric approaches to semisupervised learning (e.g., as in (Szummer & Jaakkola, 2002; Chapelle, Weston, & Schölkopf, 2003; Belkin & Niyogi, 2003; Zhu, Ghahramani, & Lafferty, 2003), which rely on an accurate estimation of the manifold in order to propagate label information.

Future work should investigate how to better handle the curvature problem: imagine that most nearest neighbor pairs are too far for the locally linear approximation of the manifold to be approximately valid between them. One way to deal with this would be to follow the manifold using the local tangent estimates, and search from or sample from manifold-following paths between pairs of neighboring examples.

The algorithm was already extended to obtain a mixture of factor analyzers in Bengio and Larochelle (2006) (with the factors or the principal eigenvectors of the gaussian centered at x obtained from $F(x)$). This view provides an alternative criterion to optimize $F(x)$ (the local log-likelihood of such a gaussian), that suggests a way to estimate the missing information

(the variances along the eigenvector directions). On the other hand, since we can estimate $F(x)$ everywhere, a more ambitious view would consider the density as a “continuous” mixture of gaussians (with an infinitesimal component located everywhere in space). According to that view, the model implicitly defines a distribution P by specifying how to stochastically go from a sample x_t from P to another nearby sample x_{t+1} , e.g. according to a gaussian centered on the manifold surface near x_t and whose principal components span the tangent plane.
