Western cultures encourage self-construals independent of social contexts, whereas East Asian cultures foster interdependent self-construals that rely on how others perceive the self. How are culturally specific self-construals mediated by the human brain? Using functional magnetic resonance imaging, we monitored neural responses from adults in East Asian (Chinese) and Western (Danish) cultural contexts during judgments of social, mental and physical attributes of themselves and public figures to assess cultural influences on self-referential processing of personal attributes in different dimensions. We found that judgments of self vs a public figure elicited greater activation in the medial prefrontal cortex (mPFC) in Danish than in Chinese participants regardless of attribute dimensions for judgments. However, self-judgments of social attributes induced greater activity in the temporoparietal junction (TPJ) in Chinese than in Danish participants. Moreover, the group difference in TPJ activity was mediated by a measure of a cultural value (i.e. interdependence of self-construal). Our findings suggest that individuals in different sociocultural contexts may learn and/or adopt distinct strategies for self-reflection by changing the weight of the mPFC and TPJ in the social brain network.

Keywords: culture; self; fMRI; medial prefrontal cortex; temporoparietal junction

INTRODUCTION

The persistent debate on self-concept in philosophy, psychology and other disciplines has inspired brain imaging studies that investigated neural representations of self-concept such as one’s own personality traits (Northoff et al., 2006; Lieberman, 2007). Using a self-referential task that requires trait judgments of oneself and a public figure (Rogers et al., 1997), researchers found increased activity associated with self-reflection in several brain regions with the medial prefrontal cortex (mPFC) as the most consistent finding (e.g. Kelley et al., 2002; Heatherton et al., 2006; Moran et al., 2006, 2009; see Heatherton, 2011 for a recent review). The mPFC may be involved in encoding of self-relevance of stimuli (Northoff et al., 2006; Han and Northoff, 2009) since trait words rated high in self-relevance increased mPFC activity (Moran et al., 2006) and mPFC activity correlated with memory performances on recall of self-related trait words (Macrae et al., 2004; Ma and Han, 2011).

As self-concept is socially constructed (Hogg, 2003), the brain activity involved in representation of the self and others may be contextually dependent and affected by sociocultural experiences. Indeed, recent functional magnetic resonance imaging (fMRI) studies have shown evidence that cultural experiences shape neural representations of personal traits of close others in relation to the self in the mPFC. Zhu et al. (2007) found that trait judgments of a close other (e.g. mother) vs a public figure activated the mPFC involved in self-referential judgments, and this effect was evident in Chinese individuals but not in English-speaking western individuals at the same threshold (the results of Chinese participants were replicated by Wang et al. (2012)). This finding suggests that shared neural representations of the self and a close other are influenced by an individual’s sociocultural experiences. The subsequent research found that, when primed with Western compared with East Asian cultural symbols, bicultural individuals showed greater mPFC activity in the contrast of trait judgments of oneself vs a close other (Ng et al., 2010). In addition, priming East Asian vs Western cultural concepts led to greater mPFC activity that differentiated between contextual vs general self-descriptions of personality traits in bicultural individuals (Chiao et al., 2009a). These findings indicate that the neural activity engaged during self-reflection is sensitive to temporal exposure to specific cultural symbols or concepts.

The previous findings of cultural differences in neural representations of the self and close others are consistent with a psychological model proposed by Markus and Kitayama (1991, 2010) which addresses cultural differences in the relationship between the self and others. According to this model, social interactions in Western cultural contexts produce a sense of self as separate or independent from others. In contrast, social interactions in East Asian cultural contexts produce a sense of self as connected to or interdependent with others. Nevertheless, there has been no direct evidence for differences in neural representations of self-construals between Western and East Asian societies. The previous studies that scanned two cultural groups did not find significant cultural group difference in mPFC activity underlying self-reflection possibly due to the small sample size used in these studies (i.e. 13 Chinese and 13 Westerners in Zhu et al., 2007; 12 Japanese and 12 Americans in Chiao et al., 2009b). Thus, it remains unclear whether the brain activity engaged during self-reflection is different between individuals who grow up in Western and East Asian cultural contexts. It is also unknown to what extent putative difference in neural activity involved in self-reflection between Western/East Asian societies is mediated by specific cultural values. Finally, although it has been known since William James (1950) that self-concept consists of different dimensions such as social roles, personality traits and physical attributes, no research has examined whether brain activities engaged in different aspects of self-concept are differentially influenced by cultural contexts, though...
a recent research suggests that the dorsal mPFC is more engaged for personal trait than physical appearance judgments, whereas the posterior cingulate is more engaged for appearance than personal trait judgments (Moran et al., 2011).

If, as claimed by Markus and Kitayama (1991, 2010), individuals in Western cultural contexts define identity in terms of inner qualities and focus on their own attributes, such cultural practices may enhance encoding of self-related stimuli compared with East Asian cultural experiences. On the other hand, if individuals from East Asian societies to a larger degree construct self-identity with reference to social relations and emphasize others’ expectations and thoughts, self-reflections may engage brain regions involved in the processing of others’ thoughts and beliefs. These predictions have not been tested directly in brain imaging research despite the recent development of cultural neuroscience studies of self-reflection (Han and Northoff, 2008, 2009; Kitayama and Park, 2010; Han et al., 2013).

In this study, we scanned college students using fMRI, during judgments of one’s own social roles, personal traits and physical attributes in a country dominated by a cultural value of independence (i.e. Denmark; Thomsen et al., 2007) and a country characterized by a high interdependent cultural value (i.e. China; Li et al., 2006). We tested the hypothesis that mPFC activity linked to encoding of personal attributes of the self vs a public figure would be greater in Danes than in Chinese. In contrast, brain regions related to mentalizing about others may be more strongly involved in Chinese than in Danes during reflection of one’s own vs a public figure’s social roles, which are key to the connection between self and others (Raeff, 2004). A candidate brain region for this effect is the temporoparietal junction (TPJ) as it is involved in understanding of others’ belief (Saxe and Kanwisher, 2003) and its lesions produce mentalizing impairments (Samson et al., 2004). The TPJ is also engaged during reflection on one’s own mental states in Westerners (Vogele et al., 2001; Jenkins and Mitchell, 2011). A recent fMRI study of Koreans found that combined judgments of personality traits and social identity on the self vs a public figure would also activate the bilateral TPJ (Su et al., 2012). In addition, the activity in the TPJ was associated with a cultural value of interdependence measured using the Self-Construct Scale (SCS; Singilis, 1994). However, as these studies scanned participants from only one culture group, it remains unknown whether participants from Western and East Asian cultural societies employed distinct patterns of neural activity in the mPFC and TPJ during self-reflection.

By comparing attribute judgments of the self and a public figure, we examined if mPFC and TPJ activities during self-reflection on personal attributes would show significant differences in Chinese and Danish participants. Furthermore, to test whether different aspects of self-construals were similarly affected by cultural contexts, we scanned the participants while they made attribute judgments across three dimensions: social roles, personality traits and physical attributes. To evaluate whether cultural values regarding self-construals (i.e. interdependence) would mediate differences in brain activity involved in self-reflection between cultural groups, participants completed the SCS (Singilis, 1994) after scanning. The measure of interdependence was then used in a mediation analysis to assess whether group differences in mPFC and TPJ activity, if any, were mediated by the cultural value of interdependence. Our work recruited 30 subjects from each cultural group and this allowed us to estimate the effect of sample size on the observed cultural group differences in the neural activity engaged in self-reflection in our study.

### Methods

#### Participants

Thirty Chinese (15 males, 18–28 years, mean age ± s.d. = 22.7 ± 1.90 years) and 30 Danish university college students (15 males, 18–28 years, mean age ± s.d. = 25.0 ± 4.09 years) were recruited in this study. All participants were right-handed, had normal or corrected-to-normal vision and reported no neurological or psychiatric diagnoses. Informed consent approved by local ethics committees was obtained from all participants prior to the study.

#### Stimuli and procedure

Stimuli consisted of two sets of items in Chinese and in Danish so that stimuli were presented in native language for each participant. The Chinese and Danish items were identical in content, were created by two psychologists and were verified by a bi-lingual speaker. Stimuli used during the scanning procedure were delivered through an LCD projector onto a rear projection screen. There were three categories of words or phrases describing the mental (i.e. personality traits, e.g. ‘diligent’ and ‘talkative’), physical (i.e. the physical appearance, e.g. ‘curly hair’ and ‘wrinkled’) and social (i.e. social roles/identities, e.g. ‘tenant’ and ‘professor’) aspects of people. Each category consisted of 80 items, and 40 items were randomly chosen for each participant (see Supplementary Table S1). Participants judged whether a given item described the self (self-judgment), a well-known gender-/nation-matched athlete (public-figure-judgment; Liu Xiang, a male Chinese athlete, and Liu Xuan, a female Chinese athlete, were used for Chinese male and female participants, respectively. Nicklas Bendtner, a male Danish athlete, and Caroline Wozniacki, a female Danish athlete, were used for Danish male and female participants, respectively) or their mother (the results of mother-judgments will be reported in an independent paper). The responding hand and the assignment of fingers to yes/no responses were counterbalanced across subjects. A font judgment (bold- vs light-faced item) was included to control for the effects of low-level sensory/perceptual processing and motor responses. Thirty trials were given for practice before the scanning procedure. Each type of judgments was presented in a single block using a block design. There were five functional scans (10 blocks/scan and 8 items/block). Each item was presented for 2 s followed by a 1 s central fixation. Two successive blocks were intervened by a 10 s fixation block. Different blocks in each scan were presented in a random order. After scanning, participants completed SCS to assess their interdependence of self-construals on a 7-point Likert scale (1 = strongly disagree, 7 = strongly agree). Interdependence was defined as sum score of interdependent items minus sum score of independent items. Higher scores indicate a greater cultural value of interdependence in self-construals. Participants’ subjective socioeconomic status was estimated using the socioeconomic status ladder (Kilpatrick and Cantril, 1960). The Inclusion of Other in the Self (IOS) scale (Aron et al., 1992) was a single-item pictorial measure to evaluate the relationship closeness of the self and public figures. Participants were presented with seven Venn-like diagrams representing different degrees of overlap of two circles and were asked to select the picture that best describes their relationship with the public figure whom participants made attribute judgments on during scanning.

#### Imaging parameters

As quantitative comparisons of contrast estimates derived from cognitive experiments can reliably be compared across two sites using the same type of scanner (Sutton et al., 2008), we collected brain imaging data from two cultural groups using identical vendor’s instrumentation and imaging parameters. Functional brain images were acquired using identical scanners (3.0-Tesla Siemens Trio) at the MRI Center for Brain Research located in the Biophysics Institute in Beijing, China, and the Center of Functionally Integrative Neuroscience located in Aarhus University Hospital in Aarhus, Denmark. Blood oxygen level
dependent gradient echo planar images (EPIs) were obtained using a 12-channel head coil (64 × 64 × 32 matrix with 3.44 × 3.44 × 5.0 mm spatial resolution, repetition time (TR) = 2000 ms, echo time (TE) = 30 ms, flip angle (FA) = 90° and field of view = 24 × 24 cm) during the judgment tasks. A high-resolution T1-weighted structural image (256 × 256 × 144 matrix with a spatial resolution of 1 × 1 × 1.33 mm, TR = 2530 ms, TE = 3.37 ms, inversion time (TI) = 1100 ms and FA = 7°) was subsequently acquired.

**Imaging analysis**

**Preprocessing**

The functional image data were analyzed by using the general linear model (GLM) for event-related designs in SPM2 (the Wellcome Trust Centre for Neuroimaging, London, United Kingdom). The functional images were realigned to the first scan to correct for head motion. Six movement parameters (translation: x, y and z; rotation: pitch, roll and yaw) were included in the statistical model. The anatomical image was co-registered with the mean realigned functional image produced during the process of realignment. The anatomical images and functional images were normalized to the standard T1 and EPI Montreal Neurological Institute (MNI) templates, respectively. Functional images were then spatially smoothed using an isotropic Gaussian kernel of 8 mm full-width half-maximum.

**Region-of-interest analysis**

Region-of-interest (ROI) analyses were conducted to test our hypotheses about the cultural group differences in the mPFC and TPJ activity associated with self-reflection. ROIs were defined using functionally defined brain regions in the previous research. As the coordinates of the mPFC activation were slightly different between Chinese and Westerners (Zhu et al., 2007), we used the coordinates of the mPFC activation of East Asian and Westerner in Zhu et al. (2007) to define the mPFC for Chinese (8/55/6) and Danes (0/51/3), respectively. The same coordinates (MNI coordinates: −6/45/5; Jenkins et al., 2008) were also used to define the mPFC for both participant groups. The results of ROI analyses based on the different or same coordinates were similar. The TPJ was constructed based on coordinates of the TPJ involved in mentalizing other’s belief (54/−54/24 and −48/−69/21 for right and left TPJ; Saxe and Wexler, 2005). Spheres with 5 mm radius were constructed with the center at the coordinates of the mPFC and TPJ. The parameter estimates of signal intensity were calculated from each ROI using MarsBaR 0.38 (http://marsbar.sourceforge.net) and subjected to a repeated-measures analysis of variance (ANOVA) with Group (Chinese vs Danish) as a between-subject variable, Judgment (self-judgment vs public-figure-judgment) and Dimension (mental, physical and social attributes) as independent within-subject variables. The ROIs defined were also used for the following sample size analysis discriminant analysis and mediation analysis.

**Whole-brain analysis**

Whole-brain analysis used a hierarchical random-effects model. In the first level, the onsets and durations of each condition were modeled using a GLM for each participant. All conditions (i.e. judgments of mental/physical/social attributes of the self/mother/public figure, font judgment and fixation) were included in the model. A box-car function was used to convolve with the canonical hemodynamic response in each condition. Contrasts between self- vs public-figure-judgments were calculated in the mental, social and physical blocks, respectively, to define neural activities related to processes of mental, physical and social aspects of the self. Random effect analyses were then conducted based on statistical parameter maps from each subject to allow population inference. Significant activations were identified using a threshold of $P < 0.05$ (false discovery rate (FDR) corrected for multiple comparisons).

To further examine the cultural difference in neural activity at the whole brain level, we first conducted a one-way ANOVA of the contrast images between self- and public-figure-judgments to assess the group differences at a voxel-wise threshold of $P < 0.001$ (uncorrected). This lenient threshold was used to define all potential brain regions engaged in self-reflection that can be further tested for cultural group differences. The $F$-statistic map representing differential activities between Chinese and Danes was then used as the masks for the small-volume correction using the WFU PickAtlas (Maldjian et al., 2003) for subsequent two-sample $t$-test at a threshold of $P < 0.05$ (FDR corrected for multiple comparisons).

See supplementary information for methods of the sample size analysis, psychophysiological interaction analysis, discriminant analysis and mediation analysis.

**RESULTS**

**Behavioral results**

Endorsement of the cultural value of interdependence was significantly greater in Chinese than in Danes ($8.13 \pm 8.85$ vs $2.45 \pm 6.49$, $t = 2.819$, $P = 0.007$), indicating a reliable cultural value difference between participants from the two societies. The subjective socioeconomic status did not differ between the two groups ($5.92 \pm 1.78$ vs $6.10 \pm 1.43$, $t = -0.440$, $P > 0.6$). The rating scores of the IOS scale did not differ significantly between Chinese and Danes (Danish (1.52 ± 1.09); Chinese (1.33 ± 0.48); $t (58) = 0.844$, $P = 0.402$), suggesting comparable relationship closeness between the self and public figures in the two cultural groups.

The ratio of ‘yes’ responses and reaction times (Supplementary Table S2) were subjected to repeated-measures ANOVAs with Judgment (self vs public figure) and Dimensions (social, mental and physical) as independent within-subject variables and Group (Chinese vs Danes) as a between-subject variable. Danes and Chinese identified comparable number of items as appropriate to describe the mental/social/physical attributes of the self and the public figure ($F < 1$). Participants responded faster to self- than to public-figure-judgments in the mental and social blocks ($F(1, 58) = 9.905$ and 75.07, $P < 0.005$), but the pattern did not differ between Danes and Chinese ($P > 0.3$). Danes responded faster to self- than to public-figure-judgments ($F(1,29) = 6.266$, $P = 0.018$), whereas Chinese showed the reverse trend ($F(1,29) = 3.912$, $P = 0.058$) during self-reflection of physical attributes.

**Brain imaging results**

**Socioculturally patterned activity associated with self-reflection**

We first conducted ROI analyses to test whether mPFC and TPJ activities showed opposite patterns of cultural group difference. The parameter estimates of signal intensity in the mPFC and TPJ were subjected to a repeated-measures ANOVA with Group (Chinese vs Danish) as a between-subject variable, Judgment (self-judgment vs public-figure-judgment) and Dimension (mental, physical and social attributes) as independent within-subject variables. This showed that self-judgments induced significantly greater mPFC activity compared with public-figure-judgments across the three dimensions ($F(1,58) = 47.527$, $P < 0.001$). However, mPFC activity underlying self-reflection was greater in Danes than in Chinese ($F(1,58) = 17.011$, $P < 0.001$). The cultural group difference in the mPFC activity was true regardless whether participants performed judgments on mental, physical or social attributes ($F(1,58) = 6.042$, 10.582 and 5.846, $P < 0.05$, Figure 1A, see Supplementary Figure S1 for parameter estimates of signal intensity
to self- and public-figure-judgments relative to font judgments in mental, social and physical blocks, respectively). The ANOVAs of the bilateral TPJ activity showed a significant three-way interaction of Judgment × Dimension × Group (left TPJ: $F(2,116) = 7.245$, $P < 0.001$; right TPJ: $F(2,116) = 7.672$, $P < 0.001$). Chinese showed significantly stronger TPJ activity than Danes during self-reflection on social attributes (left TPJ: $F(1,58) = 9.308$, $P = 0.003$; right TPJ: $F(1,58) = 8.979$, $P = 0.004$, Figure 1B) but not during self-reflection on physical or mental attributes ($P_s > 0.1$, see Supplementary Figure S2 for parameter estimates of signal intensity to self- and public-figure-judgments relative to font judgments in mental, social and physical blocks, respectively). The group differences in mPFC and TPJ activities were also significant when using differential reaction times (RTs) to self- vs public-figure-judgments as covariates in the ANOVAs (mPFC: mental: $F(1,57) = 6.634$, $P = 0.013$; physical: $F(1,57) = 6.903$, $P = 0.011$; social: $F(1,57) = 6.325$, $P = 0.015$; left TPJ and right TPJ during social attributes judgments: $F(1,57) = 11.130$ and 10.456, $P < 0.001$ and $P = 0.002$). This suggests that the socioculturally patterned mPFC and TPJ activity was evident even after excluding the potential confound of task difficulty reflected by RT differences. The opposite pattern of mPFC and TPJ activities during self-reflection on social attributes in terms of cultural differences was further confirmed in ANOVAs with Judgment (self vs public figure) and Brain Region (mPFC vs TPJ) as within-subjects variables and Group (Chinese vs Danish) as a between-subjects variable that showed significant three-way interactions (left and right TPJ: $F(1,58) = 13.147$ and 11.998, $P_s < 0.001$).

We further estimated how many subjects from each group were necessary to reveal reliable cultural differences in the neural activity during self-attribute judgments in this study. As shown in Figure 1C and D, when >24 participants were recruited from each cultural group, every calculation that compared mPFC or TPJ activity between the two cultural groups produced an absolute t-value larger than the critical t-value at the threshold of $P = 0.05$. This confirmed the robust sociocultural difference in neural activity related to self-judgments of social attributes in our samples.

To further confirm the results of ROI analyses, we conducted whole-brain analyses that compared self- vs public-figure-judgments in each cultural group. We also conducted whole-brain two-sample t-test that compared Chinese vs Danish participants during judgments of the social, mental and physical attributes, respectively. For Chinese, relative to public-figure-judgments, self-judgments on the social, mental and physical attributes activated the mPFC and the neighboring anterior cingulate (Figure 2A and Supplementary Table S3). Self-judgments on social attributes also increased activity in the precuneus and bilateral TPJ. For Danes, self-judgments generated increased activity in the mPFC in all attribute dimensions (Figure 2B and Supplementary Table S3). Whole-brain two-sample t-tests confirmed significantly greater precuneus and TPJ activity in Chinese during self-reflection on social attributes but greater mPFC activity in Danes during self-reflection on social, mental and physical attributes (Figure 2C and D).

As the aforementioned analyses showed stronger mPFC activity but weaker TPJ activity in Danish compared with Chinese participants, we next examined the relationship between mPFC and TPJ activity to assess whether the opposite pattern of mPFC and TPJ activity in terms of cultural groups also existed at the individual level. A regression analysis of all participants confirmed a significant negative correlation between the right TPJ and mPFC activity associated with self-reflection on social attributes ($r = -0.261$, $P = 0.043$).

Functional connectivity analysis was first conducted to assess the neural activity that significantly coactivated with the mPFC activity
among Danish participants.

To test whether the specific pattern of mPFC and TPJ activity during self-reflection on social attributes was driven by group differences in general processes associated with attention, semantic meaning and personal attributes, ROI analyses compared mPFC and TPJ activities associated with public-figure- vs font judgments in the social block but failed to find significant group differences (Ps > 0.1). This was further confirmed by the whole-brain analysis that revealed similar neural activations in the contrast of public-figure- vs font judgment in Chinese and Danes (Supplementary Table S4).

To test whether the specific pattern of mPFC and TPJ activity during self-reflection on social attributes was driven by group differences in general processes associated with attention, semantic meaning and personal attributes, ROI analyses compared mPFC and TPJ activities associated with public-figure- vs font judgments in the social block but failed to find significant group differences (Ps > 0.1). This was further confirmed by the whole-brain analysis that revealed similar neural activations in the contrast of public-figure- vs font judgment in Chinese and Danes (Supplementary Table S4).

**Socioculturally patterned neural activity and cultural affiliation**

Next, we conducted bootstrap and discriminant analysis to examine whether mPFC and TPJ activities related to judgments of one’s own social attributes can be used to test an individual’s cultural affiliation. Figure 4A illustrates the group specific pattern of activity in different brain regions linked to self-reflection on social attributes in a scatter plot of the mean contrast values (self- vs public-figure-judgments) calculated using bootstrap analysis (Davison and Hinkley, 1997). The distribution of Danes and Chinese in a space defined by the two vectors (mPFC and right TPJ activity) indicates a clear separation of the two groups. A Fisher’s discriminant function was conducted to further assess if the patterns of neural activity in different brain regions associated with social attributes characterized a participant’s cultural affiliation. The leave-one-out cross-validation indicated that 78.3% of cross-validated subjects were correctly classified and this was significantly higher than chance level of 50% (r(59) = 5.715, P < 0.001).

**Measure of interdependence mediates socioculturally patterned neural activity**

Finally, we examined whether the cultural differences in mPFC and TPJ activities were mediated by the cultural value of interdependence. We first tested if individual differences in cultural value of interdependence may predict mPFC and TPJ activities. Indeed, individuals’ interdependence scores were negatively correlated with mPFC activity associated with self-reflection on social attributes (r = -0.290, P = 0.025, Figure 4B). In contrast, individuals’ interdependence scores were positively correlated with bilateral TPJ activity associated with self-reflection on social attributes (left: r = 0.353, P = 0.006; right: r = 0.370, P = 0.004, Figure 4C). Then, we conducted a mediation analysis to assess whether individuals’ interdependence scores mediated the sociocultural patterns of neural activity in different brain regions. The model with cultural affiliation and interdependence scores regressed on TPJ activity was significant (left TPJ: F(2,57) = 7.514, P = 0.001; right TPJ: F(2,57) = 6.021, P = 0.004). Moreover, the effect of cultural affiliation on the bilateral TPJ activity was significantly reduced by including interdependence scores (see Table 1), suggesting that the measure of interdependence significantly mediated the relationship between the cultural affiliation and the TPJ activity involved in self-reflection on social attributes. We also conducted the Sobel test to further confirm that the interdependence was a significant mediator variable of the relationship between cultural affiliation and the TPJ activity (left TPJ: t = 2.11, P = 0.034; right TPJ: t = 1.98, P = 0.047).

**DISCUSSION**

As predicted, Chinese showed greater value of interdependence than Danes, consistent with the previous observations of dominant cultural values in the two countries (Li et al., 2006; Thomsen et al., 2007). The brain imaging results demonstrated reliable group differences in mPFC and TPJ activities involved in self-reflection. The ROI analyses showed greater mPFC activity in Danes but greater TPJ activity in Chinese in the contrast of self- vs public-figure-judgments. The results of the sample size analysis indicate that the group differences in the brain activity associated with social role judgments were highly reliable with...

**Notes:** *P<0.05, **P<0.01.

The mPFC has been repeatedly shown to be engaged in self-reflection on personality traits in both Western (Kelley et al., 2002; Heatherton et al., 2006; Moran et al., 2006) and East Asian (Han et al., 2008; Zhu et al., 2007; Ma and Han, 2011; Wang et al., 2012) cultural contexts. Our results, however, showed the first evidence that mPFC activity during self-reflection is significantly larger in individuals who grew up in a Western cultural context than those who grew up in an East Asian cultural context. This finding is consistent with our hypothesis and provides brain imaging evidence for stronger encoding of self-relevance of stimuli in the mPFC in individuals with Western cultural experiences and less interdependence compared with those with East Asian cultural experiences and more interdependence. Such cultural group differences in the mPFC activity may provide a neural basis for the independent self-construals in the Western cultural contexts and the interdependent self-construals in the East Asian cultural contexts (Markus and Kitayama, 1991, 2010).

There has so far been little evidence for cultural difference in TPJ activity engaged in encoding of one’s own attributes, though TPJ activity increased during retrieval of self-related information (Lou et al., 2004) and during reflection of one’s own current mental states in a Western cultural context (Jenkins and Mitchell, 2011). Sul et al. (2012) found TPJ activations when combining judgments of personality traits and social identity on the self vs a public figure in Koreans using a lenient threshold (i.e. a voxel level threshold of P<0.001, uncorrected, k=15). It is thus unclear whether the TPJ was equally engaged in...
self-judgments of personality traits and social identity, and whether cultural experience would influence the TPJ activity. Our results demonstrate that at a group level, the TPJ was significantly engaged during self-reflection on social attributes but not during self-reflection on mental/physical attributes. Moreover, we showed that the TPJ engagement in self-reflection on social attributes was more salient for individuals in Chinese context than in Danish context, providing evidence for a cultural influence on the TPJ activity related to self-reflection. The TPJ has been supposed to be involved in mentalizing about others’ mental states (Saxe and Kanwisher, 2003; Samson et al., 2004; Saxe and Weder, 2005) and making judgments from others’ perspective on a scene (Aichhorn et al., 2006). The TPJ activation observed in our work suggests that during self-reflection on social roles, Chinese participants may take others’ perspective or think about how others perceive or expect one’s own social roles, consistent with the idea that self-concept in East Asian cultural contexts is constructed in reference to social relations and others’ expectations and thoughts (Markus and Kitayama, 1991, 2010). The fact that the TPJ was not activated during self-reflection on mental and physical attributes suggests that the degree to which perspective taking is involved in self-reflection depends on both the dimension of the self-construal and the cultural context. It is likely that personality traits and physical attributes are thought to be more immutable compared with social roles and are thus relatively more constant across social contexts and independent of others’ thoughts. Therefore, self-reflection on personality traits and physical attributes did not engage others’ perspective and thus failed to activate the TPJ even in East Asian cultural contexts.

We found that, across our entire subject pool, mPFC and TPJ activities associated with self-reflection on social attributes were correlated with the measure of interdependence. The patterns of the associations between mPFC/TPJ activity and the interdependent self-construals are consistent with the cultural group differences in mPFC/TPJ activity, that is, the fact that participants with greater interdependence showed stronger TPJ but weaker mPFC activity was evident at both the group level and the individual level. In addition, the mediation analysis demonstrated that the group-level differences observed in our study were partially explained by individual differences in interdependence.

This socioculturally patterned neural activity during self-reflection on social attributes was also manifested in the negative correlation between the mPFC and TPJ activity, which suggests a counterbalance of mPFC and TPJ engagement during self-reflection of social attributes. Thus specific sociocultural values seem to relate to specific patterns of neural activities in key brain regions involved in social cognition during self-reflection.

Recent research has argued that self-construals are multidimensional (Hardin, 2006). Relative to Americans, Danes have been found to self-enhance considerably less, but score higher on independence, make more autonomous scenario choices and have more individual attributions about social life (Thomson et al., 2007). Thus a one-dimensional scale may not catch all of the complexities in self-construals, neither within groups nor between large imagined communities such as ‘Western’ or ‘East Asians’. It is therefore unlikely that one may reduce differences in selfhood between Westerners and East Asians, or between Danes and Chinese, to one measure of interdependence. However, our findings suggest that, in a controlled setting and with a sufficient number of participants, measuring differences in cultural values within and between groups may be a powerful method to explore the relation between cognitive universals, cultural patterning (Roepstorff et al., 2010) and specific contexts. It is likely that the patterned neural activity underlying self-reflection seen in this study may arise from the influence of patterned practice during continuous interactions of human beings in specific sociocultural contexts (Kitayama and Uskul, 2011; Roepstorff, 2011). Priming studies further indicate that these patterns are not fixed in adults but may vary as a function of the exact context of the task (Sui and Han, 2007; Chiao et al., 2009a; Ng et al., 2010).

Early brain imaging studies seemed to support that ‘self’ and ‘other’ are represented in separate brain regions. For example, the ventral mPFC was claimed to represent one’s own mental attribute (Kelley et al., 2002; Heatherton et al. 2006; Moran et al., 2006, 2009; Ma and Han, 2011), whereas the dorsal mPFC, TPJ and temporal pole were thought to be engaged in representation of others’ mental states (Frith and Frith, 2003; Saxe and Kanwisher, 2003). However, increasing evidence suggests an overlap in neural processing of information related to the self and information related to others (Legrand and Ruby, 2009). The ventral mPFC may also be activated when representing the mental states of similar or close others (Mitchell et al., 2006; Jenkins et al., 2008; Krienen et al., 2010) or when judging personal traits of a close other (Zhu et al., 2007; Wang et al., 2012). These findings indicate that representing the mind of another person may rely on reference to one’s own mental characteristics. In contrast, self-reflection on personal attributes may depend on others’ thoughts and expectations in certain cultural contexts. Han et al. (2008) found that while non-religious Chinese recruited the ventral mPFC during judgments of their own personality traits, Christian Chinese showed increased activity in the dorsal mPFC during self-reflection on personality traits. Thus beliefs and practices (e.g. Christianity) that underscore the evaluative processes of the self by others may reduce the weight of encoding stimulus self-relevance in the ventral mPFC but increase the weight of mentalizing others’ mind in the dorsal mPFC during self-reflection (Han et al., 2008). Therefore, self-reflection on personal attributes in a specific context may recruit both the dorsal mPFC (Han et al., 2008) and the TPJ (this work).

One may notice that activity in the precuneus showed a trend toward cultural difference during judgments of social attributes in the whole-brain two-sample analysis. There have been inconsistent results regarding the engagement of the precuneus in self-referential processing. Some studies observed precuneus activation during judgments on one’s own vs others’ mental attributes (e.g. Kelley et al., 2002; Moran et al., 2006), whereas other studies did not (e.g. Zhu et al., 2007; Han et al., 2008; Wang et al., 2012). The discrepancy might arise from the paradigm difference (e.g. event-related vs block design). The interesting finding of this work is that reflection on one’s own social attributes tended to activate the precuneus to a greater degree in Chinese than in Danes. Since the precuneus is associated with retrieval of information from episodic memory (Cavanna and Trimble, 2006), it is likely that, relative to Danes, Chinese may require more effort to search for personal experiences from the episodic memory during reflection on one’s own social attributes, but this must be tested in future research.

It should be noted that, while our fMRI results suggest that Westerners and East Asians may have different access to and awareness of their self, the distinct patterns of mPFC and TPJ activities in the two cultural groups may be specific to reflection on one’s own attributes. Cultural differences in the processing of self-related information in other domains may not be necessarily associated with these brain regions. Indeed, our recent event-related potential research found that the neural activity involved in recognition of one’s own face was different between Chinese and British individuals (Sui et al., 2009, in press), but this cultural difference only focused over the frontocentral region. Thus, the distinct patterns of neural activity involved in self-related processing in Western and East Asian cultures may be domain specific.

Taken together, our findings suggest that a distributed neural network consisting of brain areas including the mPFC and TPJ can be engaged in neurocognitive processing of information about both the
self and others. Individuals in different sociocultural contexts may learn and/or adopt distinct strategies, and at a neural level, this may be implemented by increasing the weight of a specific node in the neural circuit when processing self- or other-related information. The distinct socially patterned neural activity during self-reflection found at a group level may correspond to discrepant meanings ascribed to social roles in East Asian and Western cultural contexts. Our findings thus support the idea that social cognition is particularly sensitive to cultural background and contextual effects and that the mPFC and TPJ may be key areas that are differentially evoked (Vogeley and Roepstorff, 2009).
