ABSTRACT

Introduction: Mental health inpatients smoke at higher rates than general population smokers. However, provision of nicotine-dependence treatment in inpatient settings is low, with barriers to the provision of such care including staff views that patients do not want to quit. This paper reports the findings of a survey of mental health inpatients at a psychiatric hospital in New South Wales, Australia, assessing smoking and quitting motivations and behaviors.

Methods: Smokers (n = 97) were surveyed within the inpatient setting using a structured survey tool, incorporating the Fagerström Test for Nicotine Dependence, Reasons for Quitting Scale, Readiness and Motivation to Quit Smoking Questionnaire, and other measures of smoking and quitting behavior.

Results: Approximately 47% of smokers reported having made at least one quit attempt within the past 12 months, despite nearly three quarters (71.2%) being classified as in a “precontemplative” stage of change. Multinomial logistic regressions revealed that self-reporting “not enjoying being a smoker” and having made a quit attempt in the last 12 months predicted having advanced beyond a precontemplative stage of change. A high self-reported desire to quit predicted a quit attempt having been made in the last 12 months.

Conclusions: The majority of smokers had made several quit attempts, with a large percentage occurring recently, suggesting that the actual quitting behavior should be considered an important indication of the “desire to quit.” This paper provides further data supporting the assertion that multimodal smoking cessation interventions combining psychosocial and pharmacological support should be provided to psychiatric inpatients who smoke.

INTRODUCTION

Smoking rates among persons with a mental illness are 2–3 times higher than in the general population (Australian Institute of Health and Welfare, 2007). Smokers with mental illness are also more dependent on nicotine (Australian Institute of Health and Welfare, 2007), less likely to quit smoking (Diaz, Rendon, Velasquez, Susce, & de Leon, 2006; Hagan, Delneo, Hrywna, & Williams, 2008), and more likely to suffer smoking-related illnesses and increased medical morbidity (Davidson, Judd, Jolley, Hocking, & Thompson, 2001; Jones et al., 2004) than other smokers. The highest rates of smoking and nicotine dependence have been found among mental health inpatients (Lineberry, Allen, Nash, & Galardy, 2009) with smoking prevalence reported to be as high as 42%–78% (Carosella, Ossip-Klein, & Owens, 1999; Lineberry et al., 2009; Prochaska, Gill, & Hall, 2004; Solty, Crockford, White, & Currie, 2009).

Despite this burden of illness, little else is known about the smoking characteristics of this vulnerable subgroup of smokers, including their quitting motivations and behaviors.

Although the advent of smoke-free policies and smoking bans in health care facilities in developed Western nations may have increased the attention toward tobacco use in general health care settings (Freund et al., 2008; McNally et al., 2006; Ratschen, Britton, & McNeill, 2008), there seems to have been a slower adoption of change in mental health care settings and lower levels of attention toward addressing tobacco use for mental health patients (Prochaska, Gill, et al., 2004; Ratschen, Britton, & McNeill, 2008).
“Motivation to quit” is an important construct in the smoking cessation process (Coleman, 2010); although the literature reflects some lack of consensus on how such “motivation” is defined and measured (Borland et al., 2010; West, 2005). In the general population, “high” motivation levels as measured by self-reported determination to quit have been associated with seeking out and using evidence-based cessation support (Challenger, Coleman, & Lewis, 2007). Further, a range of motivational factors including explicit self-reported “wanting to quit,” financial and health concerns and expectancies, and attitudes to smoking, have been found to predict making a quit attempt, among general population smokers (Borland et al., 2010).

In contrast to the views commonly reported by mental health clinicians (Price et al., 2007; Wye et al., 2009), the limited research that has investigated the “motivation to quit” among smokers with a mental illness suggests that substantial proportions of such smokers do want to quit (Moeller-Saxone, 2008; Siru, Hulse, & Tait, 2009). Utilizing the Transtheoretical Model (TTM) of behavior change (Prochaska & DiClemente, 1983), the prevalence of future “readiness to quit” among community samples of persons with schizophrenia and related psychotic disorders (Addington, et-Guebaly, Addington, & Hodgins, 1997; Baker et al., 2007; Etter, Mohr, Qarin, & Etter, 2004; Tidey & Rohsenow, 2009), and those with depression (Acton, Prochaska, Kaplan, Small, & Hall, 2001; Prochaska, Rossi, et al., 2004; Tsoh & Hall, 2004), has ranged between 21% and 49%; similar to that indicated for general population smokers (26%–41%) (Etter et al., 2004; Tidey & Rohsenow, 2009). Research has also found between 19% and 38% of smokers with a mental illness to be contemplating quitting within the next month (Keizer, Descloux, & Eytan, 2009; Price et al., 2007; Siru, Hulse, Khan, & Tait, 2010; Solty et al., 2009). Further, research has demonstrated that such motivation can be translated into successful quitting; with quit rates of up to 22% being achieved among such persons when combined psychosocial and pharmacological interventions are utilized (Banham & Gilbody, 2010).

Studies such as those cited above, however, investigating interest in quitting among persons with a mental illness, have for the most part been restricted to considering specific diagnostic subgroups in community settings, particularly patients with schizophrenia and depression (Acton et al., 2001; Addington et al., 1997; Baker et al., 2007; Etter et al., 2004; Prochaska, Rossi, et al., 2004; Tidey & Rohsenow, 2009). A broader understanding of quit intentions among persons with a mental illness is required, and may be particularly important for inpatient clinical staff, given their role in implementing systematic provision of nicotine-dependence treatment for diagnostically heterogeneous patient populations. The few studies that have examined motivation to quit among mental health inpatient samples (Carosella et al., 1999; Siru et al., 2010; Solty et al., 2009) have been somewhat limited in their assessment—using a variety of stage of change measures, with comparisons between the studies being difficult. To the authors’ knowledge, no studies have examined the predictors of readiness to quit or quit attempts among mental health inpatients. However, among psychiatric outpatients, who may in essence be the same patient population though in a different stage of wellness and treatment, research has suggested a positive linear relationship between the number of previous quit attempts and levels of intrinsic motivation and stage of change for quitting among those with schizophrenia (Addington et al., 1997; Baker et al., 2007). Further, a greater endorsement of the “cons” of smoking has been associated with contemplating quitting, and a greater desire for abstinence among outpatients with depression (Prochaska, Rossi, et al., 2004).

Understanding the patient interest in quitting, quitting behaviors, reasons for quitting, and associated factors may assist the clinical staff in addressing tobacco use in inpatient settings, and aid the development and delivery of more effective nicotine-dependence treatment for persons with a mental illness. Given the limitations of previous research, and particularly the paucity of research undertaken within inpatient psychiatric settings, a study was undertaken to (a) examine the readiness to quit, quitting behaviors, and reasons for quitting among a diagnostically heterogeneous sample of smoking patients in a large public inpatient psychiatric hospital in New South Wales, Australia, and (b) explore whether a range of sociodemographic, clinical, and smoking-related factors predict readiness to quit and a quit attempt in the last 12 months.

**METHODS**

**Design and Setting**

A cross-sectional survey was administered to inpatients at a large public acute adult inpatient psychiatric hospital with a total smoke-free policy in New South Wales, Australia. The smoke-free policy included a total smoking ban in all hospital buildings and grounds. Voluntary patients or those able to access leave were able to leave the hospital grounds to smoke. Area health guidelines required the staff to provide nicotine-dependence treatment (including nicotine replacement therapy) to all smokers (New South Wales Department of Health, 2002); however, previous research in this setting has suggested such treatment to be inconsistent (Wye et al., 2010). The hospital had six psychiatric units, of which three were sampled for this study: one comorbid acute mental health and substance use unit, and two acute mental health units. Three units were excluded: two psychiatric emergency care units and one geriatric unit. Ethics approval for the study was obtained from the Hunter New England Human Research Ethics Committee (reference no: 08/04/16/5.10) and the University of Newcastle Human Research Ethics Committee (reference no: H-2008-0191).

**Procedure**

The survey was undertaken across a 12-month period (May 2009–May 2010) at a rate determined by the availability of interview staff—who undertook interviews on average 1 day
Readiness to quit and quit attempts among Australian mental health inpatients

The readiness to quit, and quit attempts among the surveyed and nonrespondents, and to examine associations between sociodemographic and clinical differences between respondents means, standard errors, and ranges are reported where reasons for quitting, and previous quit attempts. Percentages, smoking status, nicotine dependence (FTND), readiness to quit, and the ability to imagine life as a nonsmoker.

Analyses

IBM SPSS Statistics release version 19.0.0 (IBM, 2011) was used to analyze the data. Descriptive statistics were used to describe the sample with respect to demographic characteristics, smoking status, nicotine dependence (FTND), readiness to quit, reasons for quitting, and previous quit attempts. Percentages, means, standard errors, and ranges are reported where appropriate. Chi-square analyses were used to explore the sociodemographic and clinical differences between respondents and nonrespondents, and to examine associations between sociodemographic characteristics, smoking-related variables, the readiness to quit, and quit attempts among the surveyed participants.

Categorical variables associated at $p < .10$ were entered into multinomial backwards likelihood ratio (LR) logistic regressions to determine predictors of readiness to quit and quit attempts in the last 12 months. To facilitate the conduct of chi-square and subsequent multinomial logistic regression analyses, the following demographic, smoking, and motivational variables were condensed into two categories: marital status, cultural identification, diagnosis, previous admission, nicotine dependence, enjoy being a smoker, imagine life as a nonsmoker, and the stage of change for quitting. The remaining variables were reduced to three categories: age, admission length, and smoking duration; self-reported level of addiction; and the self-reported desire to quit.

RESULTS

Participants

A total of 757 patients were admitted to the three study units during the survey period, of whom 214 (28.3%) were approached for participation and 543 were not. The majority of those not approached ($n = 494$, 91.0%) were not present in a unit and/or eligible for inclusion on any day when the interviewing occurred, including nearly a quarter of whom had short admissions of 3 days or less ($n = 109$). A small percentage of patients were excluded on the basis of being mentally or physically unable to complete the interview ($n = 46$, 16.1%) or being less than 18 years of age ($n = 3$, 0.4%). Of those patients who were approached, 199 (93.0%) consented to participate, with full interviews able to be completed for 181 patients.

Survey participants were mostly males (56.9%), aged 31 years or older (70.7%; $M = 37.2$, $SE = 1.2$), single (55.8%), and not of Aboriginal or Torres Strait Islander descent (96.1%). The most common diagnoses were mood disorders (42.0%) and schizophrenia and related psychosis (38.1%). The majority of participants had previously been admitted to the facility (53.6%), with 40.9% admitted for between 8 and 31 days, with an average length of stay of 30.9 days ($SE = 5.9$). Chi-square analyses indicated no differences in sociodemographic or clinical characteristics between respondents and nonrespondents (i.e., those who were not approached or who declined participation).

Smoking Status and Smoking-Related Characteristics

Just over one-half of survey participants identified themselves to be smokers, 53.6% ($n = 97$). In accordance with the study’s sampling frame, approximately one-third of the smokers were drawn from each of the three study units ($n = 35$, 32, and 30). Smoking rates however differed significantly by unit, with a higher reported rate of smoking in the comorbid acute mental health and substance use unit (83.3%; 35/42 survey participants) than the two acute mental health units where the smoking rates were 44.4% (32/72) and 44.8% (30/67) ($\chi^2(4) = 15.7$, $p = .002$). The quit ratio (calculated as the proportion of ex-smokers to ever smokers [Pierce, Aldrich, Hanratty, Dwyer, & Hill, 1987]) for the sample was 26.0%. Chi-square analyses revealed a significantly lower quit ratio for participants of the comorbid acute mental health and substance use unit (12.5%), than the two acute mental health units (28.9% and 34.8%; $\chi^2(2) = 6.6$, $p = .04$).

Participants began smoking regularly at a mean age of 16.8 years ($SE = 0.5$), had smoked for an average 20.4 years ($SE = 1.3$), and 40.6% smoked 11–20 cigarettes per day. The majority (54.6%) were classified as nicotine dependent (FTND ≥6).
Readiness to quit characteristics of the sample are described in Table 2. Aside from smoking rate and quit ratio, no other differences in smoking-related characteristics were identified between units or diagnostic groupings. (Fagerström et al., 1996). The single item level of addiction scale (1–10) indicated the majority of smokers (62.1%) and reported addiction levels ranging from 8 to 10. Almost 30% of the participants indicated that they did not “enjoy being a smoker,” and when asked to imagine life as a nonsmoker, 50% of the participants reported it to be hard (Table 1). Aside from smoking rate and quit ratio, no other differences in smoking-related characteristics were identified between units or diagnostic groupings.

### Readiness to Quit

Readiness-to-quit characteristics of the sample are described in Table 2.

#### Factors Associated With a Readiness to Quit (Contemplation, Preparation for Action)

Chi-square analyses indicated that three variables were associated with having advanced beyond a “precontemplative” stage of change, at p < .10: ability to imagine life as a nonsmoker, responding “No” to “Do you enjoy being a smoker?”, and having made a quit attempt in the last 12 months. The final regression model revealed that two of the three variables entered into the model independently predicted falling into the contemplative stages of change (contemplation or preparation for action): Having made a quit attempt within the previous 12 months (OR = 4.6, df = 1, p = .02), and responding “No” to “Do you enjoy being a smoker?” (OR = 7.2, df = 1, p = .01), Table 3.

### Previous Quit Attempts

Characteristics of previous quit attempts are detailed in Table 4. Nearly half (46.9%) of the smokers had made at least one quit attempt in the last 12 months.

#### Factors Associated With Making a Quit Attempt in the Last 12 Months

Chi-square analyses indicated that three variables were associated with making a quit attempt in the last 12 months at p < .10: responding “No” to “Do you enjoy being a smoker?”; the stage of change for quitting, and the self-reported desire to quit. The final model revealed that only one of the three variables—a self-reported desire to quit between 8 and 10—significantly predicted making a quit attempt within the previous 12 months (OR = 11.9, df = 1, p = .03), compared to those self-reporting a desire of 1–3, Table 3.

### Reasons for Quitting

Smokers scored a total score of 2.7 (SE = 0.1) on the RFQ scale (Curry et al., 1990), with an intrinsic–extrinsic score of 0.4 (SE = 0.1). Scores were highest for intrinsic health concerns (M = 3.1, SE = 0.1), followed by immediate reinforcement.

DISCUSSION

This study adds substantively to our knowledge of smoking and quitting behaviors and motivations among mental health inpatients. The results demonstrate that while a majority of smokers were classified at the time of the survey as “precontemplative” with respect to the readiness to quit, a desire to quit smoking was evident in that the great majority had made quit attempts in the past (82%) and 47% had done so within the last year. Consistent with previous studies, the quit ratio for the current sample was lower than general population rates (Généreux, Roya, Montpetit, Azzoud, & Gratton, 2012; Zhu, Wong, Tang, Shi, & Chen, 2007), and similar to previously reported quit ratios for persons with a mental illness (Lasser et al., 2000; Sung, Prochaska, Ong, Shi, & Max, 2011). Despite a low quit ratio, reflecting a low likelihood of quit attempts translating into successfully maintained smoking cessation, a large proportion of those making a quit attempt in the last 12 months indicated a period of abstinence of more than a month.

Importantly, there is a need to inform clinical staff about the significant proportion of their clients who are making attempts to quit smoking, and to emphasize that the evident low success rate of such attempts should only serve to further highlight the need for clinical staff to provide appropriate nicotine-dependence treatment in the inpatient setting and to facilitate postdischarge smoking cessation support. Further, while the rate of smoking was higher among patients in the comorbid mental health and substance use unit, as previously observed in this population (Ferron et al., 2011; Solty et al., 2009), no differences were evident by unit or diagnostic grouping, or other demographic or clinical descriptors considered, with respect to the readiness or the desire to quit, or the number of previous quit attempts. Given that previous research has indicated the mental health staff to provide nicotine-dependence treatment selectively based on their perceptions of patient receptivity to care, and the desire to quit (Wye et al., 2009), our findings reinforce the need to provide smoking cessation care routinely and systematically rather than selectively to a particular type of patient (Borrelli, Lee, & Novak, 2008; Freund et al., 2009). Additionally, the proportion of participants making a quit attempt in our sample was similar to the rates reported in psychiatric outpatient samples (Ferron et al., 2011). This finding is encouraging and suggests pervasive attempts to quit despite the presence of acute psychiatric symptoms. Clinicians should be made aware of their patients’ ongoing attempts to quit, particularly given the clinical opportunity provided by the inpatient stay; where patients may be in a restricted smoking environment for an extended period, with access to clinical and pharmacological support (American Psychiatric Association, 1996; New South Wales Department of Health, 2002).

In examining the factors associated with currently being in a contemplative (as opposed to precontemplative) stage of change, only two factors were identified as predictors: a quit attempt within the last 12 months and an indication of not enjoying being a smoker. In examining the factors associated with a quit attempt in the last 12 months, only a high self-reported desire to quit (8–10, on a 10-point scale) was identified as a predictor. These findings are consistent with research among psychiatric outpatient samples indicating that making a recent quit attempt (Addington et al., 1997; Baker et al., 2007) and endorsing negative aspects of smoking (Prochaska, Gill, et al., 2004) are associated with a greater desire to quit. Further, evidence from general population smokers suggests that motivational factors predict quit attempts (Borland et al., 2010), and the number of previous quit attempts is positively correlated with the intention to quit (Marques-Vidal et al., 2011). Together, these results suggest that actual quitting behavior
may be an important indicator of the “desire to quit” in the inpatient psychiatric setting.

The finding that not enjoying being a smoker predicted readiness to quit is supported by similar previous research indicating that patients who endorse the “cons” of smoking are more likely to be contemplating quitting, and show greater desire for abstinence (Prochaska, Rossi, et al., 2004). In a recent systematic review examining the predictors of quitting smoking in the general adult population, studies revealed that having a negative opinion of smoking was also predictive of making a quit attempt, and that greater enjoyment of smoking was negatively associated with making a quit attempt (Vangeli, Stapleton, Smit, Borland, & West, 2011). Our findings also suggest that participants were almost equally divided in their ability to imagine their life as a nonsmoker (hard vs. easy). While there has been limited research on the topic of smoking identity, some researchers suggest that developing a “nonsmoker” identity predicts the motivation to quit, and quit attempts (Moan & Rise, 2005; van den Putte, Yzer, Willemsen, & de Bruijn, 2009), and may prevent relapse after making a quit attempt (Segan, Borland, Hannan, & Stillman, 2008; Vangeli, Stapleton, & West, 2010; West, 2006). Relapse prevention may be a particularly pertinent intervention strategy for this population, given that a substantial proportion of smokers in our sample indicated a recent quit attempt of more than a month; however, the quit ratio of the total sample was low. Clinicians may routinely identify smokers who report high levels of enjoyment from smoking, and place an emphasis on the negative attributes of smoking (e.g., health, cost, smell, social stigma), and assist in the development of a nonsmoker identity (e.g., removing smoking paraphernalia from home and car, saying “I am a nonsmoker” to proffered cigarettes, etc.). Future research into “smoker identity” and its use as a practice approach in clinical settings may potentially improve cessation rates among this group (Vangeli et al., 2010).

Smokers reported slightly higher levels of intrinsic versus extrinsic motivation on the RFQ (Curry et al., 1990); however, the little difference between intrinsic and extrinsic scores suggests that participants were equally influenced by both types of motivation. Overall, scores on the RFQ were similar to those in outpatient psychiatric samples (Baker et al., 2007; Marshall et al., 2009), and higher than those in the general population samples (Curry et al., 1997; Marshall et al., 2009). As previously found among smokers with a mental illness (Baker et al., 2007; Marshall et al., 2009), and in the general population (Curry et al., 1997; Marshall et al., 2009), participants cited health concerns as the most important reason for quitting; however, scores on immediate reinforcement were almost equally as high. Having intrinsic concerns about the effect of smoking on health has been found to be associated with more advanced readiness to quit (Curry et al., 1997) and has been shown to predict making a quit attempt among general population smokers (Vangeli et al., 2011). Interventions among this population could focus on enhancing intrinsic motivation types (such as self-control) and harnessing immediate reinforcement type motivations. Contingency management, for instance, has shown some promise in reducing smoking behaviors among smokers with schizophrenia and opioid-maintained patients (Dunn, Saulsgiver, & Sigmon, 2011; Tidey, Rohsenow, Kaplan, Swift, & Reid, 2011).

This study was conducted across four units located at one site, and as such the generalizability of the findings may be limited. However, given that similar smoke-free policies are now compulsory in many hospitals internationally (House of Commons Health Committee, 2005), these findings are likely to be of relevance in other inpatient psychiatric facilities. Further, the possibility of bias, particularly the influence of social desirability through the use of self-report data in this study, cannot be discounted. However, as the interviewers were independent of clinical care, and participants were not enrolled in a smoking cessation trial, the risk of such bias may have been reduced.

In conclusion, these results suggest that actual quitting behavior should be considered as an important indication of the “intent to quit.” The high proportion of respondents reporting a quit attempt, paired with the low quit ratio of this sample, suggest that targeted, comprehensive smoking cessation interventions are required. These findings will enable mental health staff to be better informed and hence assist in removing barriers to the provision of nicotine-dependence care for this significant population of smokers, and facilitate the provision of nicotine-dependence treatment. Integrated, combined, and evidence-based psychosocial and pharmacological interventions are required within mental health and addiction treatment settings to improve quit success.
