Report of COVID-19 associated with mortality in a vaccinated lung transplant recipient serves as a warning to other immunocompromised patients.
#TxID #COVID-19 #Vaccination #Transplant
Abstract
We describe a vaccinated lung transplant recipient who experienced a fatal outcome associated with COVID-19. Tocilizumab was administered. The patient exhibited clinical and radiographic evidence of colitis during the course of multiple secondary infections. This report emphasizes the need for more conservative precautions to prevent COVID-19 infection in transplant recipients.

Key Words
COVID-19, solid organ transplantation, tocilizumab, vaccination, invasive fungal infection, colitis
In a scientific triumph, the unprecedented efficacy of novel vaccination strategies has afforded millions of Americans a robust level of protection against COVID-19 and its multifarious complications. Unfortunately, whereas adverse outcomes attributed to COVID-19 in vaccinated members of the immunocompetent majority are uncommon, the risk of hospitalization and death remain tangible for patients with immunocompromising conditions.

In March 2021, a patient in their 60s who underwent lung transplantation more than five years prior received the Ad26.CoV2.S vaccine. The patient had excellent allograft function, no history of recent rejection, and was maintained on stable doses of prednisone, tacrolimus, and delayed-release mycophenolate at the time of vaccination. 62 days later, the patient developed fever, cough, and dyspnea. Social history was significant for work at a correctional facility associated with more than 250 cases of COVID-19. Admission occurred on day five of illness. SARS-CoV-2 PCR was positive. Sequencing identified the B.1.1.7 (alpha) variant. Chest X-ray demonstrated diffuse pulmonary infiltrates. Providers discontinued mycophenolate and prednisone on admission. Despite prompt treatment with dexamethasone and remdesivir, the patient required intubation three days after admission and received tocilizumab at that time. After experiencing a series of complications including severe hypoxemia and renal dysfunction requiring dialysis, the patient developed progressively worsening shock on day 16 of illness. Empiric vancomycin and aztreonam were initiated in the setting of a listed penicillin allergy. The patient progressed to require nearly maximal vasopressor support and supplemental oxygen delivery, and the infectious disease team was consulted. Documentation suggested prior carbapenem tolerance, and the patient was transitioned to meropenem, vancomycin, micafungin, and voriconazole. The patient’s vasopressor requirement improved dramatically over the course of several hours. CT of the chest on day 17 of illness demonstrated diffuse pulmonary infiltrates with a ground-glass predominance and coalescent consolidations (Figure 1A). Simultaneous CT of the abdomen demonstrated significant thickening of the sigmoid colon (Figure 1B). Despite initial clinical improvement with empiric antimicrobials, the patient sustained a fatal cardiac arrest on day 17 of illness. Purulent secretions from a tracheal aspirate subsequently grew mucoid Pseudomonas aeruginosa and Candida albicans. Blood cultures grew Clostridium innocuum and Candida albicans. Serum CMV PCR resulted at 267 IU/mL. Stool PCR for Clostridioides difficile was negative. Qualitative SARS-CoV-2 anti-spike IgG obtained on day 16 of illness was positive. Semi-quantitative SARS-CoV-2 anti-spike IgG obtained on day 17 of illness was positive, detected at a concentration of 70.4 U/mL. The patient passed away before nucleocapsid IgG testing was performed.

Similar to the diminished responses observed with other vaccines after transplant, a growing body of literature strongly suggests that immunosuppression may significantly impact the immunogenicity of COVID-19 vaccines1,2,3. A minority of lung transplant recipients mounted a detectable humoral response to vaccination in multiple studies2. In a particularly concerning recent publication, zero of 21 lung transplant recipients assessed four to six weeks after receiving a second dose of the BNT162b2 vaccine exhibited detectable anti-spike IgG4. Compared with mRNA-based strategies, the single dose of the Ad26.COVID2.S vaccine may be associated with a lower seroconversion rate in SOT recipients3. Other risk factors including recent transplantation, corticosteroid use, mycophenolate use, triple immunosuppression, lymphopenia, and advanced age have also been associated with a suboptimal humoral response to COVID-19 vaccination in transplant recipients5. In contrast to the suboptimal seroconversion rates observed in lung transplant recipients after vaccination, convalescence after natural infection has been associated with an anti-spike IgG seroconversion rate of 85% in this population5. The reasons for this observed discordance, whether related to differences
in the timing of antibody assessment after vaccination or infection, recovered patients representing a population enriched with more immunologically fit hosts, or true differences in the ability of virus and vaccine in eliciting a humoral response, have not been elucidated.

Suboptimal vaccine immunogenicity may predispose to increased rates of adverse outcomes in SOT recipients. In a recent series describing outcomes in transplant recipients who contracted COVID-19 after vaccination, one of seven patients exhibited detectable anti-spike antibodies. Five of seven patients required admission, a rate of hospitalization substantially higher than would be expected in immunocompetent hosts. In another recent series describing 55 vaccinated SOT recipients, 27% required hospitalization, more than 10% required admission to the intensive care unit, and more than 5% died. A single patient in this series exhibited detectable anti-spike IgG prior to COVID-19 infection.

While studies like these demonstrate a substantial risk of adverse outcomes in SOT recipients despite vaccination, less clear is an optimal, standardized strategy to assess the immunogenicity of vaccination and correlate immunogenicity with vaccine efficacy in this population. In the general population, mean neutralizing antibody titers after vaccination appear to correlate with protection from symptomatic infection. However, the humoral response is not the only factor involved in patient outcomes. Patients with genetic defects resulting in the complete absence of B-cell function have recovered from infection. Recent high quality data suggest that convalescent plasma administered to patients at risk for adverse outcomes does not appear to prevent the progression of disease. Monoclonal antibody therapy administered to ambulatory patients within seven days of symptom onset appears to confer clinical benefit, but small numbers of immunocompromised hosts in some studies limit direct extrapolation to the transplant population. Vaccination in lung transplant recipients has been shown to elicit detectable responses in CD4 and CD8 T-cells despite the absence of a detectable humoral response, but the clinical utility of T-cell assays in predicting vaccine efficacy has not been defined.

In this case, a transplant recipient experienced a fatal outcome despite the qualitative detection of anti-spike IgG related to vaccination and/or the response to COVID-19 infection. Whereas qualitative antibody detection may not correlate with outcomes, high absolute antibody levels generated during the course of infection correlate more strongly with decay in viral load and decreased mortality. Furthermore, a rapid humoral response may also correlate with a lower risk of mortality. Suboptimal vaccine response, rapid decline in immunity after vaccination, and a delayed, less robust response to infection are all factors that may have contributed to this patient’s severe disease. The clinical significance of absolute anti-spike IgG levels identified in the transplant population may be more challenging to ascertain without the availability of a standardized assay allowing providers to correlate immunogenicity with vaccine efficacy.

In an effort to address the suboptimal response to vaccination observed in immunocompromised hosts, the Centers for Disease Control and Prevention recently recommended that SOT recipients who previously received two doses of either the BNT162b2 or mRNA-1273 vaccine should receive a third dose. Compared to a two dose schedule, the administration of three doses of the BNT162b2 vaccine in high-risk patients has been associated with decreased rates of infection including severe illness. In SOT recipients, the administration of three doses of the mRNA-1273 vaccine appears to result in enhanced humoral and T-cell responses. Based on recent data demonstrating improved immunogenicity and high efficacy after repeat dosing, forthcoming guidelines may
recommend that immunocompromised hosts receive a second dose of the Ad26.COV2.S vaccine\textsuperscript{16}.

Finally, this case underscores the risk of secondary infections in immunocompromised patients afflicted with COVID-19. This patient’s duration of intubation predisposed to pneumonia related to \textit{Pseudomonas aeruginosa}. This pathogen is more frequently isolated from lung transplant recipients\textsuperscript{17}. In cases of definitively proven secondary bacterial pneumonia occurring during the course of severe COVID-19 infection, \textit{Pseudomonas aeruginosa} is commonly identified\textsuperscript{18}. The simultaneous isolation of both \textit{Candida} and \textit{Clostridium} species from blood suggested a polymicrobial source of infection in this case. These pathogens often associated with abdominal infection correlated with the marked bowel pathology observed on imaging. Intestinal complications including perforation have been associated with COVID-19 infection\textsuperscript{19}. Though profound shock may have contributed to the bowel pathology noted in this case, the most prominently affected portion of the bowel appeared proximal to Sudeck’s point, a site classically associated with watershed ischemia\textsuperscript{20}. Serum CMV viral loads may not always correlate well with invasive gastrointestinal disease, but it is more likely that the low level identified in this case represented nonspecific, mild reactivation in the setting of critical illness. This finding highlights the importance of carefully monitoring for CMV reactivation at weekly intervals in SOT recipients receiving augmented immunosuppression\textsuperscript{21}. IL-6 antagonism has been associated with intestinal pathology including perforation both in patients with rheumatologic conditions and those with COVID-19\textsuperscript{22,23}. Clinical symptoms in this scenario may be muted and atypical. Although tocilizumab administration may have a role in the treatment of severe COVID-19, multiple prominent studies assessing the efficacy of this intervention have excluded transplant recipients from enrollment\textsuperscript{24,25}. In the absence of more substantive studies assessing the role of biologic therapy in immunocompromised hosts, providers should exercise caution when considering agents such as tocilizumab in transplant recipients. Clinicians should have a lower threshold to evaluate for intraabdominal pathology in patients with COVID-19 experiencing clinical decompensation, especially in hosts with immunocompromising conditions and those receiving IL-6 antagonists.

In light of recent trends in the spread of the B.1.617.2 (delta) variant as well as novel variants that may represent the end result of recombination events, this work emphasizes the ongoing importance of more conservative precautions to avoid COVID-19 infection in transplant recipients\textsuperscript{26}.
