Isopentenyltransferase (IPT) is a critical enzyme in the cytokinin biosynthetic pathway. The expression of IPT under the control of a maturation- and stress-induced promoter was shown to delay stress-induced plant senescence that resulted in an enhanced drought tolerance in both monocot and dicot plants. This report extends the earlier findings in tobacco and rice to peanut (Arachis hypogaea L.), an important oil crop and protein source. Regulated expression of IPT in peanut significantly improved drought tolerance in both laboratory and field conditions. Transgenic peanut plants maintained higher photosynthetic rates, higher stomatal conductance and higher transpiration than wild-type control plants under reduced irrigation conditions. More importantly, transgenic peanut plants produced significantly higher yields than wild-type control plants in the field, indicating a great potential for the development of crops with improved performance and yield in water-limited areas of the world.

Keywords: Crop improvement • Drought resistance • Isopentenyltransferase • P5ARK • Peanut • Transgenic plants.

Abbreviations: BA, N6-benzyladenine; IPT, isopentenyltransferase; MS, Murashige and Skoog; SIM, shoot induction medium; TD-NMR, time domain nuclear magnetic resonance.

Introduction

Environmental stresses such as drought, salinity and extreme temperatures are major factors that cause significant losses in agricultural productivity worldwide (Boyer 1982, Boyer and Westgate 2004, Barnabas et al. 2008). Water availability is the major limiting factor for food production in many countries, with agriculture consuming about 75% of water in developed countries and close to 90% of water in many developing countries (Boyer 1982, Pennisi 2008). The expected increase in human population with the concomitant demands in food and urban water use and the increased weather variability due to global climate change will require a more efficient production of food crops under limited input farming systems (Pennisi 2008, Battisti and Naylor 2009, FAOUN 2010, Long and Ort 2010). The primary challenge in agricultural sciences today is to develop technologies that will increase food production and the sustainability of agriculture under environmentally limiting conditions.

Over the last 10 years, many genes that display altered expression patterns in response to environmental stresses have been identified (Bray 2004, Shinozaki and Yamaguchi-Shinozaki 2007) and the functions of some of these genes have been studied in detail (Vinocur and Altman 2005, Lemaux 2008, Lemaux 2009, Mittler and Blumwald 2010). Several genes that confer drought tolerance have been tested in the field for many years and a few are waiting for the approval of commercial release at US federal regulatory agencies (Castiglion et al. 2008, Yang et al. 2010).

The first group of genes selected for biotechnological application include genes encoding transcription factors that control gene expression under stress conditions (Century et al. 2008). For example, overexpression of a maize gene, i.e. ZmDREB2A, in Arabidopsis led to increased drought and heat tolerance in transgenic plants (Qin et al. 2007), because DREB2A regulates expression of both dehydration-inducible genes and heat shock-related genes (Sakuma et al. 2006). This gene appears to have great value in developing heat- and drought-tolerant crops in the future. In addition to the DREB/CFB class of transcription factors, of which ZmDREB2A is a member (Liu et al. 1998), other classes of transcription

1904
factors were also found to be effective in conferring drought tolerance (Umezawa et al. 2006, Shinozaki and Yamaguchi-Shinozaki 2007, Yang et al. 2010). For example, overexpression of a stress-inducible gene, SNAC1, significantly improved drought tolerance in transgenic rice and increased seed yields by 23–34% under severe drought conditions in the field (Hu et al. 2006). Overexpression of a maize transcription factor gene, ZmNF-YB2, conferred increased drought tolerance in transgenic corn plants in the field as well (Nelson et al. 2007). The ZmNF-YB2-overexpressing plants demonstrated improved performance in photosynthesis and stomatal conductance, and maintained higher chlorophyll content and lower leaf temperatures under water deficit conditions (Nelson et al. 2007).

Besides progress made in expressing stress-related transcription factor genes in transgenic plants, overexpressing genes that are involved in stress signal transduction pathways or overexpressing functional protein genes also resulted in increased drought tolerance in transgenic plants (Lemaux 2008, Lemaux 2009). For example, overexpression of a tobacco protein kinase gene NPK1 led to significantly increased tolerance against freezing, heat and salt in transgenic plants (Kovtum et al. 2000). The constitutive expression of the kinase domain of NPK1 could improve drought tolerance in transgenic maize (Shou et al. 2004). Furthermore, when a rice ortholog of NPK1 was expressed under the control of a water deficit-inducible promoter, it improved yield production by 23% under rain-free field conditions (Xiao et al. 2009). Another example of manipulating stress signaling pathways to increase drought tolerance in plants is to increase the sensitivity of plants to the plant stress hormone ABA. Wang et al. (2005, 2009) demonstrated that down-regulation of farnesyltransferase activity by antisense or RNAi (RNA interference) silencing led to increased sensitivity to ABA, inducing smaller stomatal apertures under drought conditions, which led to reduced water loss and increased drought tolerance (Wang et al. 2005, Wang et al. 2009).

Several reports have indicated that changes in hormone homeostasis, brought about by the expression of IPT (isopen­tetyltransferase, a key enzyme in the biosynthesis of cytokinin), under the control of P_{SARK}, a maturation- and stress-induced promoter, resulted in enhanced drought tolerance (Rivero et al. 2007, Rivero et al. 2009, Rivero et al. 2010). Increased cytokinin levels led to increased drought tolerance in tobacco plants (Rivero et al. 2007), enhanced photorespiration (Rivero et al. 2009) and the protection of the photosynthetic apparatus under stress (Rivero et al. 2010). The notion of a cytokinin-induced change in hormone homeostasis during stress with a concomitant enhanced drought tolerance was supported recently in transgenic rice plants expressing P_{SARK}:IPT (Peleg et al. 2011). The transgenic rice plants displayed relatively low levels of yield penalty after the plants were exposed to a severe drought episode during flower development, the most stress-sensitive developmental stage.

Although the beneficial role of cytokinin production during stress has been demonstrated both in dicot (Rivero et al. 2007) and monocot plants (Peleg et al. 2011), these studies were conducted in greenhouse conditions. Here we present evidence of the role of enhanced cytokinin in protecting plants against the deleterious effects of water deficit under field conditions. We show that transgenic peanut plants expressing P_{SARK}:IPT are significantly more drought tolerant than wild-type control plants growing under restricted water conditions in the field. The transgenic peanut plants produced between 51 and 65% more seeds than wild-type controls when tested in two consecutive years under field conditions. Our data support the notion that the production of cytokinins offers an effective strategy for the production of drought-resistant plants with improved yield under stress.

**Results**

**Introduction of IPT into peanut**

The P_{SARK}:IPT construct (Rivero et al. 2007) was introduced into the peanut genome (New Mexico Valencia A variety) by using the Agrobacterium-mediated transformation method described by Sharma and Anjaiah (2000). Transgenic peanut plants were identified by PCR amplification of the IPT transgene using genomic DNA isolated from leaves of putative transgenic plants (T₁ generation). Approximately 50% of the >60 independent lines tested contained the IPT transgene (Fig. 1A) . Plants that were positive in the PCR analysis were subjected to a mild drought stress for 5 d to induce expression of the IPT transgene through the action of the drought-inducible SARK promoter (Peleg et al. 2011). The presence of the IPT transcript was detected by RNA blot analysis (Fig. 1B) . Genomic DNAs from four transgenic lines were isolated and subjected to DNA blot analysis. Because the restriction enzyme HindIII does not cut within the IPT transgene and only one band was found in

**Fig. 1** Molecular analysis of transgenic peanut plants. (A) PCR analysis of transgenic plants. WT, wild-type; lanes A–M, 13 independent putative transgenic peanut plants. (B) RNA blot analysis of transgenic plants. Lanes 1–15, transgenic peanut plants that tested positive in the PCR experiment. 18S rRNA was used as the RNA loading control. (C) DNA blot analysis of four transgenic peanut plants. Lanes WT, 3, 7, 11 and 13, wild-type and four independent transgenic lines.
these four lines (Fig. 1C), we concluded that these four lines were all single insertion transgenic lines. These single insertion lines were used for comparative study in the laboratory and in the field.

**Expression of IPT in peanuts enhances drought tolerance**

Under full irrigation conditions, wild-type controls and three independent transgenic lines (3, 7 and 11) displayed no significant differences in biomass (Fig. 2) or in photosynthetic performance (Fig. 3) after these plants were grown in a growth chamber for 2 months. To test if \( P_{SARK}\text{-IPT} \) transgenic peanut plants are more drought tolerant, we conducted reduced irrigation experiments in growth chambers. Wild-type controls and the three independent transgenic lines were first grown under normal growth conditions for 15 d and, during this period, all plants were roughly the same size and did not display phenotypic differences (Fig. 4A). Watering was then stopped for 15 d. On day 31, plants were watered every 6 d with only a quarter of the water amounts used normally (a previous experiment determined that 600 ml of water would completely soak the 11 liter pot without water leaking out of the pot). Following a further 45 d of growth under the reduced irrigation condition, \( P_{SARK}\text{-IPT} \)-peanut plants were bigger and bushier than the wild-type plants (Fig. 4B). The root systems of the \( P_{SARK}\text{-IPT} \)-peanut plants were larger than those of wild-type peanut plants (Fig. 4C). The fresh shoot weight and the fresh root weight of the \( P_{SARK}\text{-IPT} \)-plants were significantly higher than those of control plants (84 and 188%, respectively, Fig. 5A, B). Similar results were obtained for dry shoot weight and dry root weight (61 and 124% increase, respectively, Fig. 5C, D).

The phenotypic differences displayed by wild-type and \( P_{SARK}\text{-IPT} \)-peanut plants grown under water-limiting conditions suggested dramatic differences in plant growth and development between the two genotypes under drought. The photosynthetic performance of wild-type and \( P_{SARK}\text{-IPT} \)-plants under reduced irrigation conditions was measured. The photosynthetic data were collected after the plants were grown under reduced irrigation condition for 45 d. \( P_{SARK}\text{-IPT} \)-plants displayed photosynthetic rates that were at least 2-fold higher than those of the wild-type plants (Fig. 6A). The transpiration rates of \( P_{SARK}\text{-IPT} \)-plants were also significantly higher than that of control plants (about twice as high, Fig. 6B), probably due to the higher stomatal conductance of the transgenic plants (60% higher, Fig. 6C).

The water deficit treatment caused considerable biomass reductions among all plants, but the penalty was significantly more severe in wild-type plants than that in \( P_{SARK}\text{-IPT} \)-peanut plants (81% reduction in wild-type vs. 65% reduction in \( P_{SARK}\text{-IPT} \)-peanut plants). In comparing the photosynthetic performance of these two genotypes, the water deficit treatment also caused a larger penalty in wild-type plants than in \( P_{SARK}\text{-IPT} \)-peanut plants (77.5% reduction vs. 36.4% reduction, respectively). It is clear that the higher photosynthetic rates observed in \( P_{SARK}\text{-IPT} \)-peanut plants are responsible for a larger biomass in all \( P_{SARK}\text{-IPT} \)-peanut plants.
Growth of P_{SARK::IPT}-peanut plants under water-limiting conditions in the field

To analyze the performance of the P_{SARK::IPT}-peanut plants in the field under water-limiting conditions, wild-type and three independent P_{SARK::IPT}-peanut lines 3, 7 and 11 were grown at the USDA-ARS Experimental Farm in Lubbock, Texas in the summer of 2009. These plants were treated as grown under dryland conditions, and were flood-irrigated when a long period of no rain conditions occurred. No effort was made to measure gas exchange parameters with these plants, but genomic DNAs were prepared from each plant for PCR analysis and the final yield data were collected at the end of the growth season. In 2010, two more lines were tested in addition to the four lines tested 1 year earlier: a non-transgenic line (regenerated from tissue culture) and another independent transgenic plant line (i.e. 13) at the USDA-ARS Experimental Farm in Lubbock, Texas. These plants were treated differently: reduced irrigation (19 mm per week, low irrigation group) and regular irrigation (38 mm per week, high irrigation group). Photosynthetic performance of the plants in the low irrigation group was analyzed in the middle of August. Our data indicated that the photosynthetic rates of the transgenic plants were
generally higher than those of control plants (Fig. 7A), but the differences, although significant, were smaller than what was observed for these plants under reduced irrigation conditions in the growth chamber. Similar data were obtained for transpiration rates and stomatal conductance (Fig. 7B, C).

The transgenic peanut plants in the low irrigation group grew faster after germination and quickly established a larger area within 2 months after planting in the field (Fig. 8A). This difference remained until the end of the growth season because the above-ground dry biomass from transgenic plants was significantly higher than that of wild-type controls (Fig. 8B). In 2009, we observed yield increases between 35 and 80% from the three independent PSARK::IPT-peanut lines, with an average increase of 65% (Fig. 9A); whereas in 2010, we found that the transgenic plants in the low irrigation group produced 35–79% more peanuts than wild-type plants, with an average increase of 51% (Fig. 9B). No statistical differences in yield between the wild-type and transgenic lines were observed when the plants were grown under high irrigation conditions (Fig. 9C). The low irrigation-induced yield penalties were 62% in the wild-type plants and 45, 30, 52 and 46% in transgenic lines 3, 7, 11 and 13, respectively. Although field conditions differed considerably between 2009 and 2010 (Table 1), our results showed that the transgenic plants grown under low irrigation conditions outperformed the wild-type plants in both years.

There were no differences in the oil content between wild-type control and transgenic peanut plants (Table 2). The contents of major fatty acids in peanut, palmitic acid (C_{16:0}), oleic acid (C_{18:1}) and linoleic acid (C_{18:2}) were also similar between wild-type control and transgenic peanut plants (Table 2). The minor fatty acids such as stearic acid, gadoleic acid and behenic acid varied a little between wild-type control and transgenic peanut plants; however, this difference in minor amino acid composition was also found between the wild-type and a tissue culture regenerated line (Table 2). It is clear that IPT expression in peanut does not affect oil content and major fatty acid composition.

**Discussion**

We have shown that expression of PSARK::IPT under reduced irrigation conditions improves drought tolerance in transgenic peanut plants, which is consistent with what Rivero et al. (2007) and Peleg et al. (2011) had demonstrated in tobacco and rice plants, respectively. The IPT-expressing peanut plants are visibly much larger in size than wild-type plants under reduced irrigation in a growth chamber (Fig. 4B) and in dryland conditions in the field (Fig. 8A). Their biomass is also significantly higher than that of wild-type plants in both growth chamber and field conditions (Figs. 5, 8B). These differences are probably due to higher photosynthetic rates observed with the IPT-expressing peanut plants in these conditions (Figs. 6, 7). The higher yields in the transgenic peanut plants correlate well with the increases in photosynthesis, stomatal conductance and transpiration, supporting the notion of a
cytokinin-mediated protection of photosynthesis in the transgenic plants (Rivero et al. 2009, Rivero et al. 2010). This report is the first example showing that IPT-expressing transgenic plants could produce significantly higher yields (58% more seeds on average based on the data of 2 years) in dryland conditions in the field (Fig. 9), indicating the potential for this approach to be used to improve crop production in water-limited areas of the world.

During the peanut transformation, we observed a higher rate of abnormal young seedlings in tissue culture with the PSARK::IPT construct, an indication that the IPT gene was probably expressed during the regeneration process, which affected the auxin/cytokinin ratio and led to abnormal seedlings that could not grow into fertile plants. However, when transgenic plants were obtained from tissue culture, most of them looked normal and behaved like wild-type plants under normal growth conditions, suggesting that the P_SARK::IPT construct does not affect transgenic peanut plants in negative ways. The IPT gene under the control of a senescence-inducible promoter from a gene called SAG12 (Gan and Amasino 1995) was introduced into wheat, but no grain yield increase was observed.
The IPT-expressing wheat plants did display delayed leaf senescence, increased cytokinin content, nitrate influx and nitrate reductase. This is interpreted to mean that the delayed senescence by the SAG12::IPT construct might also delay metabolite translocation from leaves to developing grains, which in turn affects grain yield (Sykorova et al. 2008). Zhang et al. (2010) recently reported that the SAG12::IPT construct was introduced into cassava, and they observed increased drought tolerance and delayed senescence in the transgenic cassava plants. Again, no increased yield was observed, perhaps due to a similar reason to that in the case in wheat. Other studies with SAG12::IPT transgenic plants also did not report significant improvement in yields (Ma 2008). It is clear that the promoters used in these experiments play a critical role in the impact of overexpression of IPT on the yield of transgenic plants.

Bhatnagar-Mathur et al. (2007) introduced the Arabidopsis drought-inducible transcription factor gene AtDREB1A into peanut and observed increased transpiration efficiency under drought conditions. However, the report did not show whether the drought-inducible AtDREB1A expression in peanut plants could improve peanut yield under water deficit or reduced irrigation conditions in the field or in laboratory conditions. The AtDREB1A-expressing peanut plants displayed reduced stomatal conductance under drought conditions, which is in contrast to our data showing that all IPT-expressing peanut plants have higher stomatal conductance (Figs. 6, 7). Perhaps this is due to different mechanisms that impact drought tolerance in transgenic plants. The DREB1A transcription factor functions in ABA-independent signaling pathways, which regulates expression of genes that are involved in drought, salt and cold stresses (Shinozaki and Yamaguchi-Shinozaki 2007), whereas the expression of IPT driven by the SARK promoter leads to altered hormone metabolism, especially increased expression of brassinosteroid-related genes and repression of
jasmonate-related genes (Rivero et al. 2010, Peleg et al. 2011). This differential expression of genes resulted in hormonal cross-talk and robust root development [i.e. 2–3 times more root biomass in transgenic peanut plants (Fig. 5)], which could increase the water-absorbing capacity of transgenic plants, allowing higher stomatal conductance even under drought conditions that ensures higher CO2 supply to leaf tissues and therefore a higher photosynthetic rate. Consequently, \( P_{\text{SARK}} \cdot \text{IPT} \)-peanut plants outperform wild-type plants under reduced irrigation conditions and in field conditions. The seeds from \( P_{\text{SARK}} \cdot \text{IPT} \)-peanut plants are normal in terms of oil content and composition (Table 2), indicating that no negative changes have been introduced into transgenic peanut and the nutritional value of transgenic peanut seeds is still the same. In summary, we have shown that regulated expression of IPT can indeed significantly improve drought tolerance in transgenic peanut plants and IPT can be an excellent gene for engineering other crops for increased drought tolerance.

**Materials and Methods**

### Peanut transformation

The *Agrobacterium* strain EHA104 harboring the binary vector \( P_{\text{SARK}} \cdot \text{IPT} \) (Rivero et al. 2007) was used for peanut transformation.

WT, wild-type; NT, non-transgenic peanut coming from tissue culture; 3, 7, 11 and 13, four independent IPT-transgenic peanut plants. Oil content and fatty acid composition are in percentages (%). \( C_{16:0} \), palmitic acid; \( C_{18:0} \), stearic acid; \( C_{18:1} \), oleic acid; \( C_{18:2} \), linoleic acid; \( C_{20:0} \), arachidic acid; \( C_{20:1} \), gadoleic acid; \( C_{22:0} \), behenic acid; \( C_{24:0} \), linolenic acid.

The SE is given. *significant at 5%; **significant at 1%; n = 5 seeds for each line.

A single colony of the *Agrobacterium* strain was grown overnight at 28°C in LB medium (pH 7.2) containing 100 mg l\(^{-1}\) rifampicin, 50 mg l\(^{-1}\) streptomycin and 50 mg l\(^{-1}\) kanamycin, to late log phase (OD\(_{660}\) = 1.0–1.5). Bacterial cells were collected by centrifugation, resuspended in fresh M5 medium (Murashige and Skoog 1962) and left on the shaker for at least 1 h. Mature seeds of peanut (*Arachis hypogaea* L., New Mexico Valencia A) were surface-sterilized by rinsing with 70% (v/v) ethanol for 1 and 10 min with 0.1% (w/v) aqueous mercuric chloride followed by several washes in sterile water. Seeds were left in sterile water for 2 h before use. The seed coat and embryo axis were removed and each cotyledon was cut in half vertically to obtain the cotyledon explants. Freshly prepared cotyledon explants were placed in the *Agrobacterium* cell suspension for 10 min, and then air dried briefly. *Agrobacterium*-inoculated explants were blotted dry, and incubated on shoot induction medium [SIM, i.e. MS medium supplemented with 10 mg l\(^{-1}\) N\(_2\)-benzyladenine (BA), 1 mg l\(^{-1}\) 2,4-D, 30 g l\(^{-1}\) sucrose and 2 g l\(^{-1}\) phytagel, pH 5.8] for 3 d at 28°C in darkness.

Inoculated explants were transferred to fresh SIM supplemented with 300 mg l\(^{-1}\) 2,4-D, and cultured with a 16 h photoperiod at a light intensity of 200 μmol photons m\(^{-2}\) s\(^{-1}\) for an additional 2 weeks. Explants displaying multiple shoot buds were subcultured onto SIM with 250 mg l\(^{-1}\) cefotaxime and 125 mg l\(^{-1}\) kanamycin for 2 weeks to initiate selection and enrichment of transformed cells. Subsequently, proximal parts of the explants containing multiple adventitious shoot buds were excised and transferred to shoot elongation medium (MS medium supplemented with 0.5 mg l\(^{-1}\) BA, 30 g l\(^{-1}\) sucrose, 2 g l\(^{-1}\) phytagel, pH 5.8) with 250 mg l\(^{-1}\) cefotaxime and 125 mg l\(^{-1}\) kanamycin for 2–3 subcultures of 3 weeks duration each for further shoot development and proliferation. Elongated shoots were cut and rooted on root induction medium (MS medium supplemented with 1 mg l\(^{-1}\) 1-naphthaleneacetic acid, 30 g l\(^{-1}\) sucrose, 2 g l\(^{-1}\) phytagel, pH 5.8).

**Plant growth conditions in growth chamber**

Seeds of wild-type and \( P_{\text{SARK}} \cdot \text{IPT} \)-plants were sown directly in 11 liter pots filled with pro-mix BX peat moss, perlite and...
vermiculite that was well watered (Premier Brands), germinated in a growth chamber under controlled conditions (25°C, 500 μmol photons m⁻² s⁻¹, 16 h photoperiod) for 15 d and grown for another 15 d without irrigation. After that, half of the wild-type and transgenic plants were selected to receive 300 ml of water every 3 d (designated as optimal watering conditions), whereas the other half of the plants received 150 ml of water every 6 d (reduced irrigation conditions). Plants were grown for another 45 d. No water drained out of the pots in these treatments. After the above-mentioned reduced irrigation treatments were finished, biomass was determined by measuring fresh weight and dry weight. The fresh weight of each individual whole plant was measured immediately after harvest. Dry weight was measured after 48 h at 60°C in an air oven.

Molecular analysis of transgenic peanut plants

PCR and DNA blot analysis. Genomic DNA was isolated from fresh peanut leaves using the PowerPlant™ DNA Isolation Kit (Mo Bio Laboratories, Inc.). PCR was performed to screen putative transformants for the presence of the SARK/promoter/IPT cassette with oligonucleotides pSARK-F1 and IPT-R1 (the 19 nucleotide primer pSARK-F1 is specific for the SARK promoter and the 20 nucleotide primer IPT-R1 is specific for IPT). The amplification reaction was carried out in a total volume of 25 μl containing 100 ng of purified genomic DNA as template, 1 U of GoTaq DNA polymerase (Promega Corporation) and 0.4 μM of each forward and reverse primer. Cycling conditions comprised an initial denaturation at 95°C for 4 min, followed by 35 cycles of 95°C for 30 s, 56°C for 30 s, 72°C for 40 s and a final extension of 10 min at 72°C. The amplified products were electrophoresed on 1.2% agarose gels and visualized in the presence of ethidium bromide with a gel documentation system.

Aliquots of 10 μg of DNA were digested overnight with 20 U of HindIII, electrophoresed in a 0.8% agarose gel and transferred onto a Biotrans™ nylon membrane (MP Biomedicals, Inc.). The membrane was hybridized with a 32P-labeled IPT cDNA fragment (50 ng) that was amplified by PCR using the oligonucleotides IPT-F2 and IPT-R2. The probe was made through random priming using a kit (DECA Prime™ Kit, Ambion Inc.). The conditions for hybridization and washing were described in Church and Gilbert (1984). The temperature was maintained at 40°C in a growth chamber of a Li-Cor 6400. Leaf temperature was maintained at 25°C. Gas exchange measurements were carried out in the middle of August, starting at 09:00 h and continuing until 12:00 h.

Field trial experiments

The wild-type controls and transgenic lines were planted at the Experimental Farm of the USDA-ARS Cropping Systems Research Laboratory in Lubbock, Texas, in the middle of May in both 2009 and 2010 (wild-type and three transgenic lines 3, 7 and 11 were used in 2009 and wild-type, a non-transgenic line from tissue culture, and the four transgenic lines 3, 7, 11 and 13 were used in 2010). In 2009, one treatment was tested: dryland with occasional flood irrigation. In 2010, two treatments were tested: reduced irrigation (19 mm per week) and high irrigation (38 mm per week). Seeds were sown into 2 m rows at a density of 20 seeds m⁻¹ and a 100 cm row spacing in a 16 row block in 2009 and a 24 row block in 2010. Individual plants were randomly selected each time from IPT-containing peanut lines for gas exchange analysis, and other physiological data such as weight of peanut seeds and dry weight of above-ground biomass were collected at the end of experiments.

Peanut oil analysis

Oil content analysis. Time domain nuclear magnetic resonance (TD-NMR) experiments were carried out on a Bruker Minispec MQ10 NMR Analyzer with a tube of 25 mm diameter. The temperature was maintained at 40°C. Data were acquired using the Minispec software (Bruker), and the data oil program (Bruker). The weighed peanut samples (about 10 g) filled the tube for analysis. The 90° and 180° pulse lengths were 11.62 and 23.44 μs, respectively. For each run, 16 scans were collected with a recycle delay of 2.00 s. The gain was set to 60 dB. The TD-NMR instrument was calibrated by eight pure peanut oil calibration standards at the concentrations of 0, 10, 20, 30, 40, 50, 60 and 70%.

Fatty acid composition analysis. Peanut seeds were cut and powdered into hexane. The solvent was evaporated in nitrogen gas and the resulting fatty acids were converted to their methyl esters using boron trifluoride as a catalyst.
in a methanol–toluene mixture at 95°C. The methyl esters were extracted into hexane and analyzed by HP 5890 gas chromatography (GC) with a flame ionization detector (FID) and a capillary column (DB-Wax, 30 m length, 0.53 mm i.d., 0.50 μm film thickness). Helium was used as the carrier gas at 30 p.s.i. A temperature program was used with an initial temperature of 200°C held for 1 min. The temperature was increased to 230°C at 3°C min⁻¹, then held for another 3 min at the final temperature. The injector was heated to 200°C and the split flow was 4 p.s.i. The detector temperature was 320°C. Fatty acids were identified by comparison with fatty acid methyl ester standards (68A) purchased from Nu-Chek Prep, Inc. Fatty acids were quantified by using the peak area percentage as a ratio to the total area of all methyl esters present.

**Statistical analysis**

Reduced irrigation experiments in a growth chamber were performed three times with 3–4 independent lines and 6–8 plants for each line each time. Means of one representative experiment are presented. The statistical significance of differences in the mean values of the examined parameters between the transgenic and wild-type plants was determined using the Student’s t-test (*P < 0.05, **P < 0.01).

**Funding**

This research was supported by the Texas Peanut Producers Board; National Peanut Producers Board; Texas Department of Agriculture; the China Scholarship Council [a 1-year fellowship to Texas Tech University to H.Q.].

**Acknowledgments**

We thank Guoxin Shen, Xunlu Zhu, Neelam Mishra, Rongbin Hu, Jian Chen, Yinfeng Zhu, Gang Pan, Saranya Ganapathy and Jaswanth Kanumuri for harvesting peanut seeds in the field or shelling the peanut pods.
