Children With Febrile Seizures Do Not Consume Excess Health Care Resources

Kevin E. Gordon, MD, MS; Peter R. Camfield, MD; Carol S. Camfield, MD; Joseph M. Dooley, MB; Peggy Bethune, MD

Background: Febrile seizures are benign but so terrifying for parents that they may subsequently view their affected children as “vulnerable.” Children viewed as vulnerable may be brought to medical attention more frequently. We examined subsequent hospitalizations and physician visits during a 6- to 7 1/2-year period for a group of children who had participated in a case-control study of initial febrile seizures.

Methods: Individual data from a regional cohort of 75 children with a first febrile seizure and 150 febrile and 150 afebrile controls were linked to 2 comprehensive provincial health services databases—a hospital admissions/separations database and a physician services database.

Results: Linkage was achieved for 98% of the study cohort, with health care utilization data for 6 to 7 1/2 years available for 96%. Children with febrile seizures had nearly identical rates of subsequent hospitalization compared with age-matched controls ($\chi^2$ test, $P = .88$). An excess of day-surgery visits for primarily otolaryngologic procedures was seen for the febrile seizure patients 0 to 12 months after their initial febrile seizure ($\chi^2$ test, $P < .001$). During the next 6 to 7 1/2 years, the febrile seizure patients had nearly identical rates of physician visits ($\chi^2$ test, $P = .15$); however, they had more visits to otolaryngologists in the first 3 to 9 months after the febrile seizure ($\chi^2$ test, $P < .001$), but fewer visits to pediatricians during the next 1 to 4 years ($\chi^2$ test, $P < .001$).

Conclusions: Children with febrile seizures have nearly identical rates of hospital and physician services utilization compared with controls. This supports the hypothesis that febrile seizures are benign, and that parents recover from their initial anxiety and do not consider their children vulnerable to additional illness in the years that follow.

FEBRILE SEIZURES are extremely frightening for parents. Most think that their child is dying during the seizure, although the epidemiological facts about febrile seizures are very reassuring. Death caused by a febrile seizure has not been reported and must be exceedingly rare, since 3% to 4% of all children will have at least 1 febrile seizure. Similarly, the risk of epilepsy is low (2%-4%) despite the risk of recurrent febrile seizures in 30% to 40% of children who have a first one. The intelligence and behavior of children with febrile seizures is convincingly the same as their unaffected siblings at ages 7 and 10 years. However, it is unclear if parents are adequately reassured by these facts.

For these reasons, we hypothesized that children might consume excess health care resources subsequent to a first febrile seizure.

Demographics

Median age at study entry was 1.3 years (range, 0.1-4.4 years); 55% were boys and 45% girls. There was no difference in age or sex composition between the children with a first febrile seizure and the control...
group. There were 482 hospitalizations and 23,097 physician contacts. The rates of physician visits and hospitalizations prior to study entry did not differ for cases and controls.

HOSPITALIZATION RATES

Children with a first febrile seizure had nearly identical subsequent hospitalization experiences compared with age-matched controls during the next 6 to 7 1/2 years after a first febrile seizure ($\chi^2$ test, $P = .88$) (Figure 1).

Post hoc results: Hospitalization rates showed an early peak, which corresponds to hospitalizations within 7 days of study entry for those children presenting to the hospitalization with fever (febrile seizures and febrile controls). Not unexpectedly, febrile children were 2.6 times more likely to be admitted than were afebrile controls during this time ($\chi^2$ test, $P = .04$). After these early admissions were accounted for, a second peak appears within the hospitalization rates, occurring 0 to 12 months after study entry for the children with febrile seizures. During this 12-month period, children with febrile seizures were 3.1 times as likely as the control children to have same-day admissions ($\chi^2$ test, $P = .003$). Most of the same-day admissions were for otolaryngologic procedures (23 of 32 [72%]). Overall, 12% of children with febrile seizures had an otolaryngologic procedure within 12 months of their initial seizure compared with 4% of the control group.

PHYSICIAN CONTACT RATES

During the subsequent 6 to 7 1/2 years after a first febrile seizure, children with a first febrile seizure had nearly identical rates of physician visits as the control group ($\chi^2$ test, $P = .15$) (Figure 2).

Post hoc results: All children had increased rates of physician visits for the 3-month period after study entry. Compared with controls, children with a first febrile seizure had a 30% increase in physician visits (an excess of 1.5 physician visits) during the first 3 months following their seizure ($\chi^2$ test, $P < .001$). These excess visits for the febrile seizure group were primarily to family practitioners and pediatricians.

Physician visits were examined by type of physician. Rates of visits to family practitioners were not sig-
There was a significant reduction in the use of pediatricians' services following a first febrile seizure. The reason for this change in utilization is unclear. Within our area, pediatricians provide predominantly consultative and emergency care. Families may require these services less often after surviving a perceived life-threatening event.

We were surprised that the experience of a febrile seizure had so little effect on subsequent health care utilization. In 1964, Green and Solnit developed the construct of the "vulnerable child." This concept implies that after a child has recovered from a potentially fatal medical condition, there is a marked discrepancy between the child's normal health, development, and growth and the parents' enduring and unfounded perception that the child continues to be at risk for serious illness and premature death. It is likely that a continuum of child vulnerability or overprotection exists for children with ongoing medical conditions. This mismatch between perceived vulnerability and true vulnerability may lead to increased use of health care resources. One study examining the persistence of child vulnerability in premature infants demonstrated that, by school age, the current perception of health is more related to current ratings of health rather than past health events. In our study, even if children with febrile seizures were initially perceived as vulnerable, their families did not respond by seeking excessive physician and hospital visits after the acute event.

The intervention offered to febrile seizure patients in our emergency department during the original study period was not completely standardized. All children were assessed by a pediatrician, most parents saw a short instructional slide-tape presentation about the benign nature of febrile seizures, and many stayed overnight in an observation unit attached to the emergency department. We have some evidence that, following this intervention and up to 2 weeks later, most families had retained the basic facts about febrile seizures, although family routines were still disrupted.

The children with febrile seizures and their families afterward were more likely to visit their family practitioners and pediatricians within 3 months, and subsequently receive specialist care. It may be possible that these

Our study shows that children who presented to an emergency department with a first febrile seizure did not have more physician contacts or hospitalizations during the next 6 to 7½ years, compared with age-matched controls who had visited the same emergency department at the same time, but for other reasons.

After the first febrile seizure, there was an increase in otolaryngologic visits and procedures for 9 to 12 months. Although otolaryngologic diseases such as otitis media and frequent sore throats have been associated with febrile seizures, otitis media was not more common at the time of presentation in our febrile seizure group when compared with the febrile control group. There is limited evidence that children with febrile seizures are more frequently infected than population-matched controls or cohort members without febrile seizures. However, both of these studies may have been limited by a recall bias on the part of parents, who were retrospectively reporting illnesses. These findings may have prompted Forsgren et al to reexamine their study group's subsequent health utilization. Parents retrospectively reported essentially identical crude rates of health care utilization between cases and controls after a 6- to 7-year follow-up, similar to our own findings.

There was a significant reduction in the use of pediatricians' services following a first febrile seizure. The reason for this change in utilization is unclear. Within our area, pediatricians provide predominantly consultative and emergency care. Families may require these services less often after surviving a perceived life-threatening event.

We were surprised that the experience of a febrile seizure had so little effect on subsequent health care utilization. In 1964, Green and Solnit developed the construct of the "vulnerable child." This concept implies that after a child has recovered from a potentially fatal medical condition, there is a marked discrepancy between the child's normal health, development, and growth and the parents' enduring and unfounded perception that the child continues to be at risk for serious illness and premature death. It is likely that a continuum of child vulnerability or overprotection exists for children with ongoing medical conditions. This mismatch between perceived vulnerability and true vulnerability may lead to increased use of health care resources.

One study examining the persistence of child vulnerability in premature infants demonstrated that, by school age, the current perception of health is more related to current ratings of health rather than past health events. In our study, even if children with febrile seizures were initially perceived as vulnerable, their families did not respond by seeking excessive physician and hospital visits after the acute event.

The intervention offered to febrile seizure patients in our emergency department during the original study period was not completely standardized. All children were assessed by a pediatrician, most parents saw a short instructional slide-tape presentation about the benign nature of febrile seizures, and many stayed overnight in an observation unit attached to the emergency department. We have some evidence that, following this intervention and up to 2 weeks later, most families had retained the basic facts about febrile seizures, although family routines were still disrupted.

The children with febrile seizures and their families afterward were more likely to visit their family practitioners and pediatricians within 3 months, and subsequently receive specialist care. It may be possible that these
visits reinforced the benign nature of febrile seizures and had a reassuring effect on their families, resolving any parental perception of vulnerability.

Because of the pattern of medical practice in our area and the emotional upset caused by a first febrile seizure, we suspect that most patients who present for medical evaluation would come to our emergency department, suggesting that our children with febrile seizures were a representative regionally based cohort.

Likewise, the selection of control groups should be commented on. For case-control studies of health care utilization, control groups are ideally drawn from a population accessing health care at the same time and location as the cases. In our original study, the 2 control groups were selected to examine the risk factors for fever independently from those for febrile seizures, and seemed ideal for the subsequent purpose of examining health care utilization. As there were no significant differences between the 2 control groups, they were combined for final analysis in that study. For this study, we chose a priori to analyze the 2 control groups together as we had done previously, while presenting the graphic results separately to demonstrate the similarity of the 2 control groups.

During the study period, the Canadian universal health care system allowed all children access to physician and hospital services. There is no parallel private health care system in our province. We used comprehensive databases to count all hospitalizations and all reimbursed physician visits. The accuracy of Canadian health administrative databases for basic demographic and visit data has been documented. Hence, the results likely reflect all hospitalizations and physician contacts for this cohort of children.

Although we are confident about the accuracy and completeness of our primary results, a note of caution must be addressed on those derived from post hoc analyses. We did not make any adjustment for multiple statistical testing of results derived from graphic analysis, raising the possibility of type I errors. Furthermore, these findings, even if valid, may be a result of local area practice. Therefore the discovery of increased visits to otolaryngologists and decreased visits to pediatricians after a first febrile seizure requires independent confirmation before generalization. If confirmed, these findings provide a fascinating insight into the clinical course of febrile seizures.

We conclude that even if a febrile seizure renders a child vulnerable in the parents’ eyes, it does not lead to long-term increased use of health care resources. Dealing with the fears of parents is important; however, physicians caring for children can be reassured that management decisions for families and their children with febrile seizures need not be driven by any concern that these children will subsequently use excess health care resources.

Accepted for publication November 24, 1999. We thank Edie Smith, RN, for her assistance with data linkage and Ellen Wood, MD, MS, for her comments during manuscript revision. Access to claims data and assistance with linkage were provided by the Population Health Research Unit, Dalhousie University, Halifax, Nova Scotia.
