

RECENT TRENDS IN TOP INCOME SHARES IN THE UNITED STATES: RECONCILING ESTIMATES FROM MARCH CPS AND IRS TAX RETURN DATA

Richard V. Burkhauser, Shuaizhang Feng, Stephen P. Jenkins, and Jeff Larrimore

Abstract—Although most U.S. income inequality research is based on public use March CPS data, a new wave of research using IRS tax return data reports substantially faster inequality growth for recent years. We show that these apparently inconsistent estimates are largely reconciled when the income distribution and inequality are defined the same way. Using internal CPS data for 1967 to 2006, we show that CPS-based estimates of top income shares are similar to IRS data-based estimates reported by Piketty and Saez (2003). Our results imply that income inequality changes since 1993 are largely driven by changes in incomes of the top 1%.

I. Introduction

THE March Current Population Survey (CPS) public use files have been the primary data source used to study income inequality trends in the United States.¹ The consensus finding of research based on these data is that household income inequality increased substantially in the 1970s and 1980s and continued to increase, but at a much slower pace starting in the 1990s (Gottschalk & Danziger, 2005; Daly & Valletta, 2006; Burkhauser, Feng, & Jenkins, 2009).

The most notable alternative source for studying income inequality trends in the United States derives from tax return data. In their seminal paper, Piketty and Saez (2003) use data

from Internal Revenue Service (IRS) statistics of income tax returns to analyze income inequality trends in the United States. Their paper used the methods of Piketty (2003), which considered top income shares in France and was one of the first in a growing literature that has used tax return data to examine income inequality trends around the world, including Atkinson (2005) for the United Kingdom; Saez and Veall (2005) for Canada; Bach, Corneo, and Steiner (2009) for Germany; Dell (2005) for Germany and Switzerland; and Atkinson and Leigh (2007) for Australia. Atkinson and Piketty (2007), Atkinson, Piketty, and Saez (2011), and Leigh (2009) provide comprehensive reviews of this literature.

One of Piketty and Saez's major contributions derives from being able to observe income inequality trends over a much longer period than previous researchers: tax return data are available for years well before any survey data on income were collected. However, their findings have also sparked debate about U.S. inequality trends in recent years. (For a flavor of the debate on this topic, see the blog postings by leading economists and others on the *Economists View* Web site, 2007.) Reynolds (2007) provides an illustration of how the work by Piketty and Saez has altered the popular view of recent trends in income inequality and a critique of their results.

In contrast to research based on CPS data that finds income inequality slowing in the 1990s, Piketty and Saez (2003, 2008) find that the share of total income (excluding capital gains) held by the very richest groups grew during the 1990s and, with the exception of the period from 2000 to 2002, continued to rise rapidly through the beginning of the twenty-first century as well. (When capital gains are included in the income measure, Piketty and Saez find that top income shares grew even faster.) What explains the differences in inequality trends that researchers found using these two types of data?

One explanation is that there are deficiencies in one or both of these data sets that limit researchers' abilities to observe the true trends in inequality. Critics of using the public use CPS to measure income inequality argue that top coding, undercoverage, and underreporting of top incomes restrict the survey's ability to observe income changes for those at the top of the distribution. Any opinions and conclusions expressed here are our own and do not necessarily represent the views of the U.S. Census Bureau. All results have been reviewed to ensure that no confidential information is disclosed. Support for this research from the National Science Foundation (award nos. SES-0427889, SES-0322902, and SES-0339191) and the National Institute for Disability and Rehabilitation Research (H133B040013 and H133B031111) is cordially acknowledged. S.J.'s research was supported by core funding from the University of Essex and the U.K. Economic and Social Research Council for the Research Centre on Micro-Social Change and the United Kingdom Longitudinal Studies Centre. S.F.'s research was supported by Leading Academic Discipline Program, 211 Project for Shanghai University of Finance and Economics. We thank Ian Schmutte, the Cornell Census RDC Administrators, and all their U.S. Census Bureau colleagues who have helped with this project. We also thank Tony Atkinson, Melissa Kearney, Andrew Leigh, Robert Moffitt, Thomas Piketty, Emmanuel Saez, and the referees for their helpful comments and suggestions on earlier versions of this paper.

¹ See Atkinson, Rainwater, and Smeeding (1995), Atkinson and Brandolini (2001), and Gottschalk and Smeeding (1997) for reviews of the income distribution literature. For more recent examples of the use of the public use CPS in measuring inequality trends in the United States, see Gottschalk and Danziger (2005) and Burkhauser, Feng, and Jenkins (2009).

1992; Slemrod, 1996; Burkhauser et al., 2003–2004; Piketty & Saez, 2006b; and Burkhauser et al., 2009.) Thus, to the extent that income inequality changes are due to changes in the top-coded portion of the CPS, researchers using these data may mismeasure trends in income inequality. Furthermore, if there are disequalizing changes arising from income sources not captured by the March CPS (such as capital gains), the CPS will also mismeasure inequality trends for an income measure that is broader than the standard CPS one.

Using IRS data to measure income inequality also has potential limitations. Critics point out that tax filers have a financial incentive to report their income in ways that limit their tax liabilities, and as a result, filing behavior is sensitive to changes in the personal income tax rate. Several fiscal manipulation strategies are sensitive to changes in marginal tax rates and income reporting rules. These include reclassifying income as either wage earnings or business profits depending on which is taxed less (Sivadasan & Slemrod, 2008), receiving untaxed fringe benefits in lieu of wage compensation (Woodbury & Hammermesh, 1992), or deferring compensation through stock options or deferred compensation packages (Scholes & Wolfson, 1992; Goolsbee, 2000). Since high-income earners are most able to adjust the way that they receive and report income, tax return data may especially not be able to capture income at the top of the distribution accurately. For example, Slemrod (1995) suggests that tax law changes since the 1970s have provided incentives for the very rich to switch their reported income from Subchapter-C corporation profits, which are not reported on personal income tax forms, to S-corporation profits and personal wage income, which are reported. This in turn may lead researchers using tax return data to overstate the actual rise in income among the very rich. (See Feenberg & Poterba, 1993, for an earlier discussion of this problem and a summary of the difficulties measuring top incomes with tax records data.)

Piketty and Saez (2003) acknowledge that this type of fiscal manipulation may affect measures of top income shares, but argue that such effects are problematic only for short-term trends rather than the long-run trends in income inequality, which are their primary concern. However, for researchers interested in the relatively short-term trends in income inequality of recent years, time shifting of income may still pose a problem. Additionally, while time shifting of income may affect income inequality only in the short term, income that is received in ways other than through labor earnings, such as through higher nontaxable fringe benefits or the reporting of wage earnings as business profits, will never be reported on personal income tax forms and thus could have implications for long-term inequality trends. Thus, to the extent that changes in reporting rules alter the way income is reported at the top of the distribution, researchers using IRS tax return data may mismeasure actual changes in income inequality.

Yet another potential explanation for the differences in estimated inequality trends is that they result from differ-

ences in the definition of income and how its distribution is summarized rather than differences in the data sources themselves. Although all researchers using public use CPS data or IRS tax data examine “inequality” in the broad sense, there are substantial differences in their definitions of “income” (the sources included—especially the inclusion of government transfers and nontaxable income in the former and its exclusion in the latter—and whether there is adjustment for differences in “needs”), the income recipient unit (tax units versus households and individuals within them), and how best to measure inequality (in terms of top income shares versus a more comprehensive measure such as the Gini coefficient).

To some extent, these differences in practice have evolved because of the nature of the data examined. For example, researchers using public use CPS data, which has a high prevalence of top-coded values at the top of the income distribution, often measure inequality using the ratio of the 90th percentile to the 10th percentile (p_{90}/p_{10}) to mitigate problems arising from topcoding. (See Burkhauser et al., 2009, for a discussion of the limitations of this measure, with CPS illustrations.) Researchers using tax return data focus on top income shares since many low-income individuals do not file a tax return, so it is not possible to directly derive measures of income inequality that take account of the income of poorer groups (Piketty & Saez, 2006a). To date, no researchers have attempted to bridge the gap between the CPS- and IRS-based literatures to determine the extent to which the differences in inequality estimates emanating from these two literatures arise from differences in the ability of these two data sources to capture top incomes or from the application of different income constructs based on these data sources. In this paper, we do just that.

Using internal CPS data, we examine income inequality trends since 1967 using the inequality measures and income distribution definitions developed by Piketty and Saez (2003) and others using tax return data. Using measures of income that exclude capital gains, we can largely match their results. Our estimates of top income share levels and trends are nearly identical for groups in the richest tenth, with the exception of the richest 1 percent. Even for estimates of the share held by the top 1 percent, the two data sources are broadly in agreement about trends over much of the past forty years. It is only during a six-year period in the late 1990s that the trends diverge for reasons that are not easily explained by changes in the nature of the two data sources.

II. Data

Our analysis derives from access to internal CPS data, which are identical to the data that Census Bureau researchers use in their official work (U.S. Census Bureau, 2009). These data measure top incomes much better than the data released in public use CPS files. To protect the confidentiality of its respondents, the Census Bureau censors (“top

codes”) each of the income sources received by individuals. This practice must be addressed in order to derive sensible estimates of top income shares using CPS data. The advantage of internal data over public use data is that the prevalence of top coding is very much lower.² For example, in 2004, 0.5% of individuals lived in a household in which some source of income was top-coded in the internal data compared to 4.6% in the public use data.

Even the small extent of censoring in the internal CPS data produces biased estimates of top income shares. To address this issue, we use a multiple imputation approach in which values for censored observations in the internal data are multiply imputed using draws from a parametric model of the income distribution fitted to the internal data. The generalized beta of the second kind (GB2) model we turn to here is widely used in the income distribution literature and shown to fit income distributions extremely well across different periods and countries (see Bordley, McDonald, & Mantrala, 1996; Brachmann, Stich, & Trede, 1996; Bاندourian, McDonald, & Turley, 2003; Feng, Burkhauser, & Butler, 2006; and Jenkins, 2009). Since the GB2 is a four-parameter distribution, its shape is more flexible than that of the Pareto distribution, which has also widely been used in the literature to describe the top of the income distribution.

The multiple imputation approach used here is the same as that used by Burkhauser et al. (2011) and described in detail by Jenkins et al. (2011). This approach first involves fitting a GB2 distribution for each year’s data by maximum likelihood, accounting for individual-level right-censoring.³ We then randomly draw values from the income distribution that is implied by the fitted GB2 distribution and impute these to censored observations, estimate inequality indices using the distribution comprising imputations for censored observations and observed incomes for noncensored observations, and repeat the whole process 100 times for each year. Estimates of inequality indices such as top income shares are derived by combining the estimates from each of the 100 data sets for each year using the averaging rules proposed by Rubin (1987), and modified by Reiter (2003), to account for imputation variability. This combination of internal CPS data with multiply imputed values for censored incomes provides the best available CPS-based estimates of the income distribution. It is the source for all the CPS-based estimates of top income shares that we com-

pare with the tax record-based estimates of top income shares of Piketty and Saez (2003).

We believe that the flexibility of the GB2 distribution allows a better fit of top incomes than the Pareto distribution but acknowledge that both distributions are widely used to impute top incomes in the inequality literature. Fichtenbaum and Shahidi (1988), Bishop, Chiou, and Formby (1994), and Piketty and Saez (2003), for example, use the Pareto distribution. Thus, in Appendix A, we explore the implications of using a Pareto imputation instead. We compare the Pareto beta coefficients describing the shape of the right tail of the distribution that are implied by our CPS data with those that we calculate from the data appendix of Piketty and Saez (2007). In general, the beta coefficients from our multiply imputed distributions are slightly smaller than those derived from Piketty and Saez’s data. This indicates that if we had assumed that a Pareto distribution with the Piketty-Saez beta coefficients described top incomes in the CPS data, the top 1% income share would be larger and even closer to their IRS-based results.

We have also undertaken all our calculations of top income shares using CPS internal data used as is, without imputations for censored values. All the conclusions regarding income shares for income groups below the top 1% are unchanged. For the top 1%, using the unaltered internal data rather than multiply imputed internal data reduces estimates of income shares, but our conclusions about trends are similar. (See Appendix A for further details.)

III. Methods: Three Definitions of the Income Distribution

There are three substantial methodological differences between research based on the CPS and research based on the IRS tax return data. The first concerns the inequality measures used. Most CPS research employs either indices such as the Gini coefficient or Theil index that use data on all incomes, or indices like p90/p10 that ignore incomes at the very top of the income distribution. In contrast, tax data researchers focus on the top of the income distribution, defining inequality in terms of top income shares—the share of total income held by the richest 10%, the richest 5%, or the richest 1%, and so on—with larger income shares indicating greater inequality.

The other two differences in method concern the definitions of income, specifically what is counted as “income” and what is the income-receiving unit. CPS-based researchers have typically defined income as pretax, posttransfer income excluding capital gains (see Gottschalk and Danziger, 2005, and Burkhauser et al., 2011).⁴ This includes all income collected on the March CPS questionnaire, which is

² For many indices of income inequality such as the Gini coefficient and members of the General Entropy class, researchers can replicate results derived from internal CPS data by using cell means of top-coded incomes that are provided back to 1975 by Larrimore et al. (2008). However, by construction, cell means assume that all top-coded individuals have the same income. As a result, using cell means to approximate top income shares with the public use CPS data will lead to an overestimation of the income held by the 90th to 99th percentile groups and an underestimation of the income held by the top 1% of the distribution.

³ To ensure that model fit is maximized at the top of the distribution, the GB2 is fitted using observations in the richest 70% of the distribution only, with appropriate corrections for left truncation in the ML procedure.

⁴ In international comparisons of income inequality, it is most common to include the effect of both government transfer programs and tax policies by measuring posttax, posttransfer income. See Atkinson and Brandolini (2001) and Gottschalk and Smeeding (1997) for reviews of this literature.

intended to capture almost all cash income that individuals receive. Two notable exceptions are realized capital gains and profit-sharing income, including stock options, which are not captured in the CPS. (See Weinberg, 2006, for a description of income sources collected and excluded in the March CPS data.) This income is aggregated to the household level and deflated using an equivalence scale to account for differences in economies of scale and “needs” (the square root of household size is a commonly used scale). Attributing the same size-adjusted household income to each individual within the same household, researchers examine the distribution of income among individuals.

Piketty and Saez (2003) and other researchers using tax data use different definitions. Piketty and Saez define income to include any income reported on IRS personal income tax returns before deductions and excluding capital gains. This encompasses “salaries and wages, small business and farm income, partnerships and fiduciary income, dividends, interest, rents, royalties, and other small income reported as income” (Piketty & Saez 2003, pp. 5–6). In addition to including stock options, which are not included in the CPS survey, a notable difference between this income definition and the CPS one is that the IRS definition excludes most transfer income, which is generally not taxable and not included in the adjusted gross income reported on tax returns. Hence it is close to the individual’s market income, which is also known as pretax, pretransfer income in the broader income inequality literature.⁵ (See Scholz & Levine, 2002; Corneo & Fong, 2008; and Bach et al., 2009, for examples of this type of measure.)

Piketty and Saez (2003) aggregate income to the level of the tax unit rather than to the level of the household, do not adjust for differences in tax unit size, and examine the distribution among tax units rather than among individuals. An important issue in this literature is that not all individuals in the United States file a tax return, with nonfilers generally having lower incomes. Therefore, estimates of the income share of the top 10% of tax filers understate the number of tax filers relative to the situation in which nontax filers are

included in the base. That is, when the number of “potential tax filing units” (filers plus nonfilers) is the base, a higher share of actual tax filers, and hence a larger share of reported pretax, pretransfer income, must be included in order to correctly measure overall income inequality. To address this issue, Piketty and Saez (2003) estimate the total number of potential tax units and calculate the number of returns that make up the top income groups using this number. They define a potential tax unit as a married couple of any age, divorced or widowed individual of any age, or single individual over the age of 20. (See the data appendix of Piketty & Saez, 2007, for further details.)

Definitions of income and the unit of analysis are important because variations in each can be expected to lead to different inequality estimates. For example, we expect the inclusion of transfer income in income (as is done by CPS researchers) to reduce measured inequality because transfer income is targeted at poorer families, while the inclusion of stock options in the IRS data likely increases inequality.

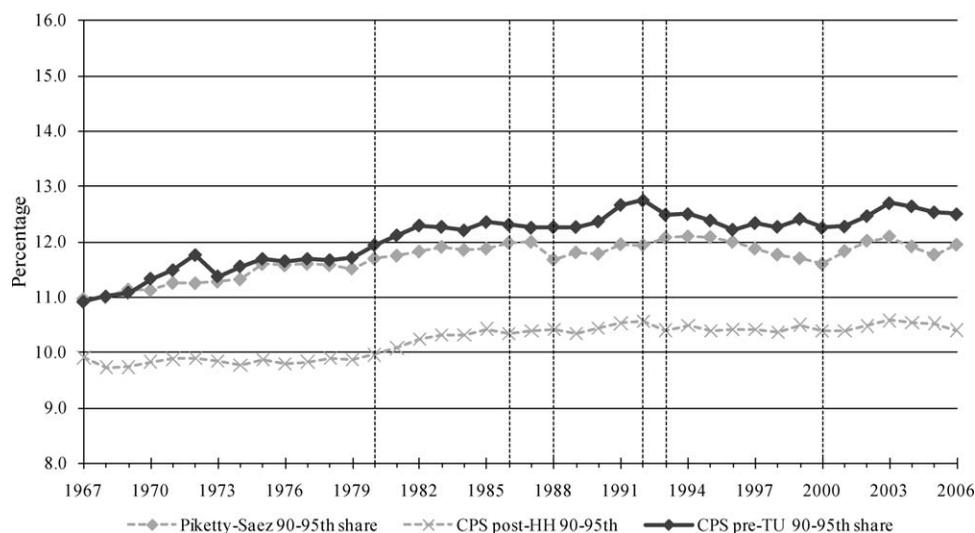

Additionally, low-income individuals who need to share costs and lower living expenses are more likely to live in larger households with individuals outside their tax unit. Therefore, aggregating income to the household level rather than the tax unit, and adjusting for economies of scale using an equivalence scale, may yield an inequality estimate that is lower than for the distribution of pretax, pretransfer income among tax units.

The two types of CPS series that we use are defined as follows. First, our traditional CPS series, labeled “CPS-Post-HH,” refers to the estimates based on the distribution of size-adjusted pretax, postcash transfer household income among individuals, excluding capital gains. Size adjustment uses the square root of household size. The second CPS-based series, “CPS-Pre-TU,” uses Piketty-Saez-type definitions of the income distribution. That is, we consider distributions of non-size-adjusted pretax pretransfer tax unit income, excluding capital gains among tax units. Since tax unit identifiers are not provided in the CPS, we follow Piketty and Saez’s procedures to determine potential tax units. All single individuals over the age of 20, married couples, and divorced or widowed individuals are considered to head a tax unit. Never-married children under the age of 20 are considered dependents and are assigned to the tax unit of their parent or guardian.⁶ Our measure of pretax, pretransfer income includes income from wages and salaries, self-employment, farm income, interest, dividends, rents, trusts, and retirement pension income, which closely matches the taxable income sources included in the IRS tax

⁵ In the wage inequality literature, researchers tend to be primarily interested in how different types of workers—low versus high skilled, women versus men, and others—are rewarded in the labor market. Hence in this literature, it is common to measure pretax wage rates or labor earnings. Pretax, pretransfer market income is an extension of this concept to cover all factors of production. Traditionally, researchers interested in income inequality have focused on how it relates to one’s ability to consume and hence include government transfers in the U.S. literature and both taxes and transfers in the international comparative literature. In those literatures, pretax, pretransfer income is rarely used by itself but rather to distinguish between incomes generated in the absence of government and a fuller measure of income that includes government taxes and transfers. In the CPS-based literature, this has generally meant including cash transfers in income, thus using a pretax, posttransfer income definition for inequality estimation. Some researchers, including the National Research Council Panel on Poverty and Family Assistance, have advocated moving even further from the pretax, pretransfer market income definition when analyzing poverty by including taxes and noncash transfers in U.S. income inequality calculations. For a further discussion of the effect of such proposals on poverty rates and income inequality, see Burtless and Smeeding (2002).

⁶ In the small number of cases where never-married individuals under age 20 live in a household without a parent or guardian, we assigned them to the tax unit of the primary family in the household or the oldest adult in the household when there is no primary family. Only if there are no adults over the age of 20 in the household are they considered their own tax unit. Different procedures for classifying these individuals were tested, including removing them from the sample and assigning them their own tax units, which produced substantively similar results.

FIGURE 1.—ESTIMATES FROM CPS AND IRS TAX RETURN DATA OF THE SHARE OF TOTAL INCOME HELD BY UNITS WITH INCOMES BETWEEN THE 90TH AND 95TH PERCENTILES, 1967–2006

Vertical lines delineate time periods displayed in table 1 and discussed in the main text.

Source: The Piketty-Saez series is taken from Piketty and Saez (2003, 2008). It refers to the distribution of pretax, pretransfer income among tax units. The CPS-based series were derived by the authors from CPS internal data. The CPS-Pre-TU series was derived using the Piketty-Saez definition; the CPS-Post-HH series refers to the distribution of size-adjusted pretax, posttransfer household income among individuals. See main text for further details.

return data that Piketty and Saez analyzed. Although a small number of taxable transfers is excluded by this definition, the broad income categories the CPS used prior to 1987 make it difficult to separate these taxable transfers from nontaxable transfers consistently across the entire period. The vast majority of transfer income is nontaxable, and so our best approximation to Piketty and Saez's income definition necessarily excludes this income source.

Matching the procedures used for Piketty and Saez's primary income series, we exclude capital gains. This exclusion is both because capital gains are not recorded in the March CPS and because "realized capital gains are not an annual flow of income (in general, capital gains are realized by individuals in a lumpy way) and form a very volatile component of income with large aggregate variations from year to year depending on stock price variations" (Piketty & Saez, 2003, p. 6). However, as illustrated in the appendix of Piketty and Saez (2003), since capital gains are primarily received by high earners and this receipt has increased over time, including capital gains would likely raise the level of inequality and its increases in recent years. This would be true using both IRS-based data, where capital gains are included by some researchers, and the CPS-based data, where capital gains are generally not included since they would have to be imputed as an addition to income recorded on the questionnaire.

Comparisons between the CPS-Post-HH and CPS-Pre-TU series are informative about how much of the difference in top share estimates can be attributed to differences in definitions, whereas comparisons between the CPS-Pre-TU series and the "Piketty-Saez" estimates reported by Piketty and Saez (2003, 2008) are informative about how much of the difference in estimates can be attributed to differences in the underlying data source.

In order to contrast the three series at several points in the income distribution, we examine income shares for three groups within the richest tenth of the distribution each year. We consider the fortunes of those with incomes between the 90th and 95th percentiles of the distribution (p90–p95 group), those with incomes between the 95th and 99th percentiles of the distribution (the p95–p99 group), and those in the top 1%.

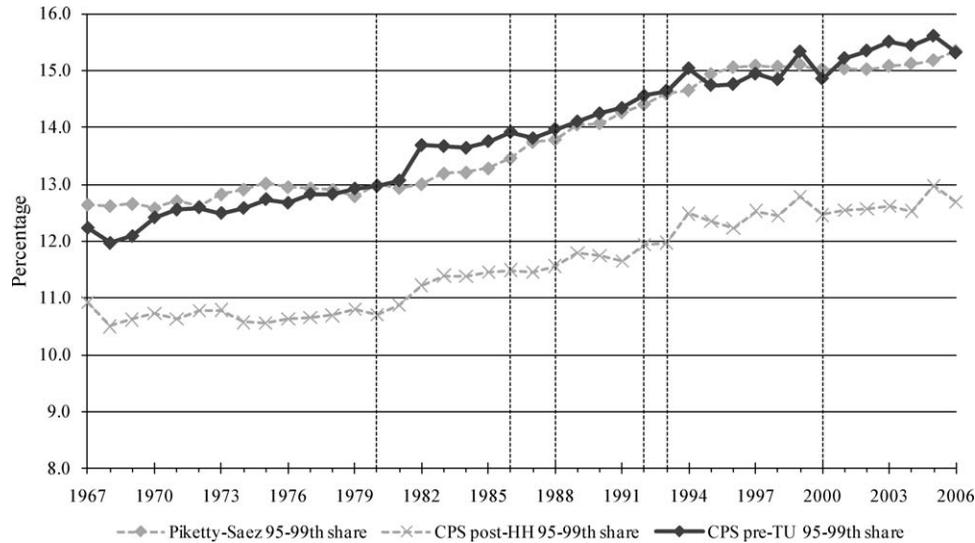

IV. Top Income Shares: IRS- and CPS-Based Series Compared

A. P90–P95 and P95–P99 Income Shares

In figures 1 and 2 we provide our estimates of top income shares for the first two of the top income series defined earlier. The income shares for the p90–p95 group are presented in figure 1, and the shares for the p95–p99 group are presented in figure 2. For both groups, the estimates of income shares according to the CPS-Post-HH series are smaller than the corresponding ones from the Piketty-Saez series. This is unsurprising given the two very different income definitions used. Because a much greater share of nontaxable government in-cash transfers—Aid to Families with Dependent Children (AFDC), Temporary Assistance for Needy Families (TANF), Social Security benefits, and so forth—are held by the poorest 90% of the pretax posttransfer (CPS-Post-HH definition) distribution, we would expect the income share of the top 10% of the pretax posttransfer income distribution to be smaller than the income share for the top 10% of the Piketty-Saez gross income distribution in all years. This is the case.

But once we control for differences in definitions, the differences in estimates of income share held by these high-

FIGURE 2.—ESTIMATES FROM CPS AND IRS TAX RETURN DATA OF THE SHARE OF TOTAL INCOME HELD BY UNITS WITH INCOMES BETWEEN THE 95TH AND 99TH PERCENTILES, 1967–2006

See figure 1 for sources and note.

income groups based on CPS and IRS data are much smaller in both level and trend. This can be seen by comparing corresponding estimates in the CPS-Pre-TU and Piketty-Saez series. For the p90–p95 group (see figure 1), the CPS-Pre-TU series and Piketty-Saez share estimates are almost identical at the beginning of the period. The increase in the CPS-Pre-TU series p90–p95 group’s income share over the forty-year period is somewhat greater than the Piketty-Saez estimates: a rise from 10.9% to 12.5%, compared to a rise from 11.0% to 11.9%. But even with the slight trend differences, the income shares in each year are always close to each other. For the p95–p99 group (see figure 2), levels and trends using the CPS-Pre-TU and Piketty-Saez series are even closer, although the CPS-Pre-TU series again shows a slightly greater upward trend than the IRS data.

In addition to comparing the income share of the p90–p95 and p95–p99 groups, we also considered the sources from which individuals in these groups received their income. However, the GB2-based multiple imputation procedure must be performed on total household income and thus cannot distinguish source-level incomes for this analysis. While this limits the usefulness of a comparison for the top 1% of the distribution, since most individuals in the p90–p95 and p95–p99 groups do not have censored incomes, we can use the unadjusted internal data to compare the sources of income for members of these groups.⁷ As discussed in Appendix B, for the p90–p95 and p95–p99 income groups, the sources of income for members of these groups are also similar between the CPS-Pre-TU series and the Piketty-Saez

⁷ While we provide the income source analysis for the top 1% in Appendix B, along with that for the lower-income groups, we strongly caution against overanalyzing the results for this group because changes in censoring thresholds over time dramatically alter the makeup of income for this group, which is not corrected for censoring using the GB2-based multiple imputation procedure.

series. This further supports the assertion that up through the 99th percentile of the income distribution, the IRS- and CPS-based results are similar once controlling for the differences in income and sharing unit definitions.

B. Top 1% Income Shares

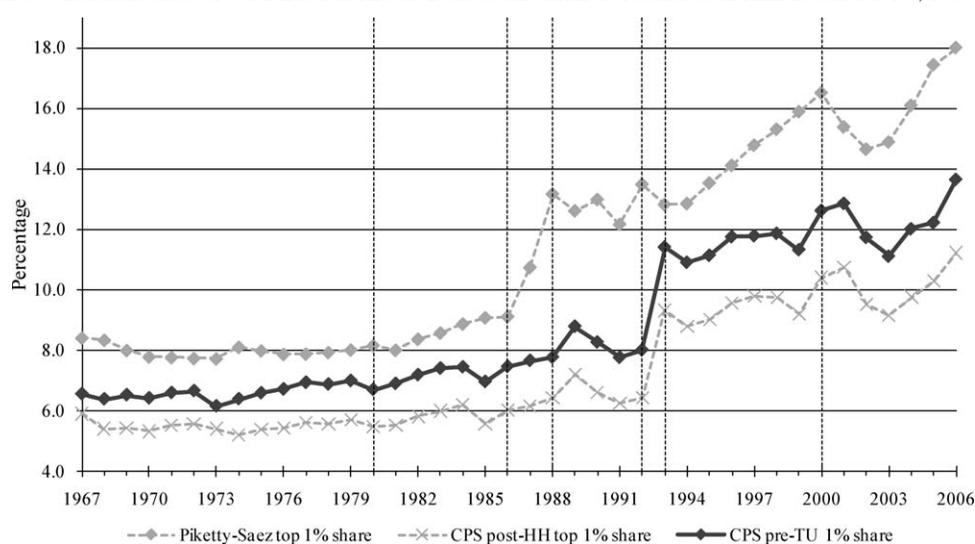

Thus far, we have restricted our attention to groups with incomes lying between the 90th and the 99th percentiles. The similarities between the income shares in the IRS and CPS data for individuals in this range should be of comfort to both IRS and CPS researchers. The similarities mean that up to the very highest incomes, the two data sets are consistent once there is reconciliation of the definitional differences described above. But what about the income shares of the top 1%?

It is only within this group that we see larger differences in results across the data sets. Figure 3 shows the income shares for the top 1% of the distribution using each of our three series. In contrast to the earlier findings for the other two income groups, when the same pretax, pretransfer income definition is used, a more sizable unexplained gap remains between the data sets. It is worth emphasizing, however, that while the remaining difference is greater than for the other two income groups analyzed, the differences in absolute terms between the CPS-Pre-TU series and the IRS series are relatively small, at least in earlier years. Before 1986, the income share for the top 1% is between 1 and 2 percentage points greater for the Piketty-Saez estimates relative to the CPS-Pre-TU series, although this difference expands in later years.

C. Trends in Income Shares

Arguably, inequality trends over time are of greater interest to researchers than inequality levels. In both the CPS-

FIGURE 3.—ESTIMATES FROM CPS AND IRS TAX RETURN DATA OF THE SHARE OF TOTAL INCOME HELD BY THE TOP 1%, 1967–2006

See figure 1 for sources and note.

TABLE 1.—AVERAGE ANNUAL PERCENTAGE CHANGE IN INCOME SHARE OF THE TOP 1%, BY SUBPERIOD BETWEEN 1967 AND 2006

Subperiod	March CPS		IRS Tax Return Data
	Size-Adjusted Pretax, Posttransfer Household Income among Individuals (CPU-Post-HH)	Pretax, Pretransfer Tax Unit Income among Tax Units (CPU-Pre-TU)	Pretax Pretransfer Tax Unit Income among Tax Units (Piketty-Saez)
1967–1980	–0.5	0.2	–0.2
1980–1986	1.7	1.9	1.9
1986–1988	3.2	2.0	22.1
1988–1992	0.0	0.8	0.6
1992–1993	45.0	42.5	–4.9
1993–2000	1.6	1.5	4.1
2000–2006	1.3	1.4	1.5

See figure 1 for sources.

Pre-TU series and the Piketty-Saez series, we find slower growth in the share of income held by the p90–p95 and p95–p99 groups starting in the early 1990s than was the case in the 1980s. Thus, both the CPS and IRS data sources suggest that whatever top income concentration occurred during the 1990s, it was largely confined to increases in the share of income held by the top 1%.

So what precisely has been happening to the share of the top 1%? Prior to 1986, the trends in the income share for this group are remarkably similar according to all three series. Table 1 shows the average annual percentage increases in the top 1%'s income share for seven subperiods. The two pre-1986 periods are the relatively low-inequality growth period of the 1970s and the higher-inequality growth period from 1980 to 1986. Each of the three series shows similarly small inequality growth in the 1970s, and the 1980 to 1986 period is even more similar as the Piketty-Saez series and two CPS series show almost identical average growth in the share held by the top 1%. It is only after 1986 that more substantial differences between the series begin to appear. The first of these differences occurs from 1986 to 1988, when the Piketty-Saez series shows a dramatic 22.1% annual increase

in the top 1% income share. The increase according to the CPS-Pre-TU series is a more moderate 2.0%.

This divergence between series subsides in the period immediately after 1988. When the CPS-Pre-TU series is used, the difference in the top 1%'s income share between this series and the Piketty-Saez one is just 0.2% per year from 1988 to 1992. Thus, when similar income definitions are used, the trends in the income share of the top 1% are similar in both data sources for the entire period between 1967 and 1992 with the exception of 1986 to 1988.

From 1992 to 1993, the trends diverge again across series. In this year, both CPS series increase by over 40% while the IRS series falls by 4.9%. It is only from 1993 to 2000 that the IRS series shows a sustained increase in the share of income held by the top 1% relative to CPS-Pre-TU series. Over this period, the Piketty-Saez series estimates that the share of the top 1% was rising at an accelerated pace. The 4.1% annual increase is more than twice the rate of increase in the early 1980s. By contrast, the CPS-Pre-TU series yields an annual increase of only 1.5% in the income share of the top 1%, a slower rate of increase than seen in the 1980s. But after the divergence for the 1990s, trends across

series converged again from 2000 to 2006, and all three series show similar increases of between 1.3% and 1.5% average annual increases in the income share of the top 1%.

So for most periods during the past forty years, the trends in top income shares are similar once similar income definitions are used. There are no major differences in the trends implied by the different sources for the income shares of those with incomes between the 90th and 99th percentiles. It is only during the periods 1986–1988, 1992–1993, and 1993–2000 that the two sources show markedly different trends, and only for the top 1% of the population.

V. Explaining the Differences in Trends in the Share of the Top 1%

While the p90–p95 and p95–p99 series are quite close across the two data sets, what explains the divergences between series in estimates of the share of the top 1% for the periods 1986–1988, 1992–1993, and 1993–2000? We argue that the results for the first two periods arise from well-known limitations of the IRS tax return data and of the CPS, respectively.

For 1986 to 1988, we argue that the increased share of the top 1% shown by the Piketty-Saez series primarily reflects a change in tax policy rather than any genuine change in the incomes controlled by the richest 1%. The Tax Reform Act of 1986 provided substantial incentives for the very richest tax units to switch reported income from Subchapter-C corporations to Subchapter-S income and wage income. (See Feenberg & Poterba, 1993; Slemrod, 1996; Saez, 2004; and Atkinson et al., 2011.) The tax law changes likely created a behavioral effect in how income is reported, which led to the very large observed increase in top income shares in IRS personal tax return data, excluding capital gains over the course of these two years.

This blip therefore primarily reflects the IRS tax records' improved ability to capture more of the income of this top income group after the 1986 Tax Reform Act. The high incomes observed after the reform were likely received by individuals at the top of the income distribution prior to the reform as well, but since personal income tax rates exceeded corporate tax rates, individuals had a financial incentive to structure their income in ways that prevented it from appearing on personal income tax forms or appearing on personal income tax forms only in the form of capital gains.⁸

In contrast, the CPS data show no such increase between 1986 and 1988 after the Tax Reform Act. We suggest that this

is because the CPS survey questions about income are broader than the detailed questions on IRS tax forms. As a result, nuances such as Subchapter-C versus Subchapter-S income that are important for taxpayers completing their tax return, and hence for the administrative records derived from them, do not have the same impact on CPS pretax income reporting. Since the CPS inquires simply about pretax income rather than making distinctions about whether the income is from a Subchapter-C or Subchapter-S corporation, the consequences of this type of reporting are of less personal consequence. Therefore, March CPS data are less sensitive than tax record data are to changes in the way in which people distinguish types of income in response to changes in tax laws.

Similarly, the divergence between the series for 1992 to 1993 reflects fundamental changes in the design of the CPS rather than a real change in income inequality. Over these years, the Census Bureau implemented a major redesign of the survey instrument, including a change to computerized rather than paper-based data collection methods. (See Ryscavage, 1995, and Jones & Weinberg, 2000, for details.) These changes, which also included allowing respondents to enter higher income values than allowed previously, improved the ability of the CPS to record all incomes, and especially top incomes. We argue that this change in measurement primarily explains the increase of more than 40% in the share of the top 1% in the CPS data during these years.

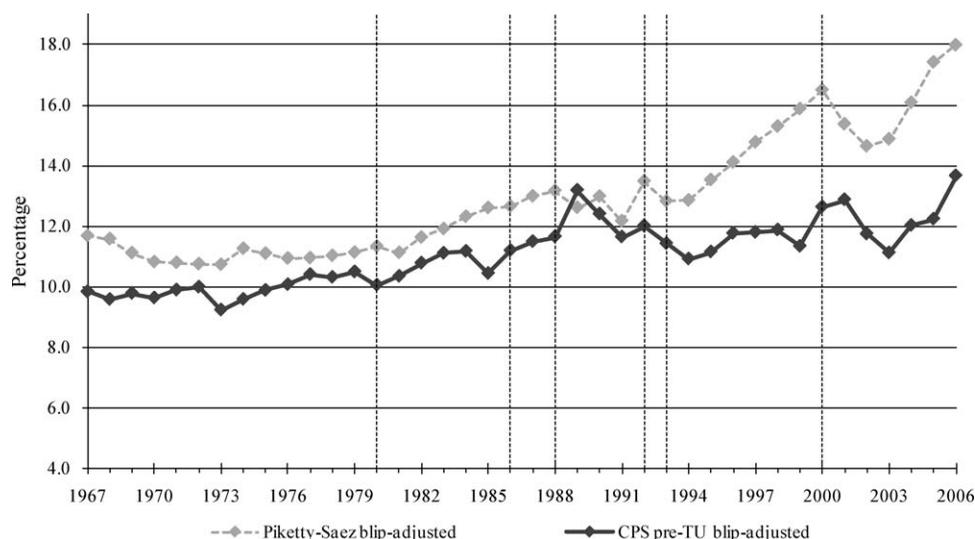

In both the case of the 1986 to 1988 increase in the IRS tax records and the 1992 to 1993 increase in the CPS data, the income shares after the blip should more accurately represent actual income at the top of the distribution. With the CPS data, this is because the survey was redesigned with the intention of improving its capability to capture top incomes, and with the IRS data, this is because top earners are now reporting more of their income in ways that are captured on personal income tax records.

Since the 1992 to 1993 increase in top income shares in the CPS data primarily reflects a change in survey design and the 1986 to 1988 increase in top income shares in the IRS tax records data primarily reflects a change in the way that tax units report their income, we explore the consequences of controlling for these artifacts of measurement. Figure 4 illustrates the level of top 1% income shares in each series over the past forty years, upwardly adjusting the top income shares prior to the blips as if the better information on top incomes now observed were available prior to 1986 in the IRS data and prior to 1992 in the CPS data.⁹ When this is done, the levels of the share of the top 1% remain within

⁸ In the appendix of Piketty and Saez (2003), the series including capital gains illustrates a decline in the top 1% income share from 1986 to 1988 rather than the large increase shown for the top 1% income share when including capital gains. This suggests that the blip observed in the IRS data excluding capital gains in these years is partially attributable to income shifting to minimize tax liabilities. However, since capital gains income increased for top earners in the 1990s, when including capital gains, there are greater increases in the top 1% income share in the IRS data in the 1990s (Piketty & Saez, 2003). These would likely exist in the CPS data as well if capital gains were captured there.

⁹ In both cases, it is assumed that the change in top 1% income shares from the other unaffected data set captures the actual change in top income share over the blip year. So, for 1986 to 1988, the change in the blip-adjusted IRS series is assumed to equal the 4.1% increase in the top 1% share seen in the CPS data, and for 1992–1993, the change in the blip-adjusted CPS series is assumed to equal the 4.9% decline in the top 1% share seen in the IRS data. The blip adjustments also have a limited effect on the p90–p95 and p95–p99 income shares as the share assigned to the top 1% shifts. Figures illustrating the blip-adjusted income shares for these series are available on request from the authors.

FIGURE 4.—ESTIMATES FROM CPS AND IRS TAX RETURN DATA OF THE SHARE OF TOTAL INCOME HELD BY THE TOP 1%, 1967–2006, ADJUSTING FOR MEASUREMENT CHANGES BETWEEN 1986–1988 IN THE IRS DATA AND BETWEEN 1992–1993 IN THE CPS DATA

The Piketty-Saez series is adjusted upward prior to 1988 to reflect the systematic undercounting of tax unit income captured in IRS personal income tax records prior to the 1986 Tax Reform Act. The CPS series is adjusted upward prior to 1993 to reflect the systematic undercounting of income from top-income households prior to the 1993 CPS redesign. To control for the difference between these measurement changes and actual changes in the blip years, it was assumed that the change in top 1% income shares from the unaffected data set reflects the actual change in the top income share over the blip years. See also the note and sources for figure 1.

2.2 percentage points of each other across the two data sets until 1994, and the trends are quite similar other than the previously mentioned divergence from 1993 to 2000.

What explains the divergences for 1993 to 2000? Several factors could distort top income share trends in both series. For example, including capital gains would likely increase top income shares in both series. Conversely, including noncash benefits (such as health insurance, food stamps, or rent subsidies), housing stock appreciation, or measuring posttax income would likely decrease top income shares in both series. However, since these factors are excluded from both data sets, they will distort top income shares equally in both. Thus, the divergence must result from income sources that are excluded in one data set but included in the other and that changed during the mid-1990s to influence the trends. Alternatively, the divergence could result from a shift in the ability of one or both data sets to capture top incomes over this period.

One potential explanation, as Reynolds (2006) suggests, is that changes in tax rules, requiring executive stock options to be reported as taxable income, led to the estimated rise in income share of the top 1% in the Piketty-Saez personal income tax series. According to this hypothesis, this group's income share has always been higher than observed (implying a greater difference between the Piketty-Saez and CPS-Pre-TU series). And importantly, trends according to the two series are more similar on the grounds that the more rapid increase in the Piketty-Saez series in the 1990s was an artifact of the changes in tax accounting rules. Alternatively, it is possible that the use of stock options increased in the 1990s and that the IRS data accurately captured this increase but the CPS data did not since the CPS does not ask about stock options. Thus, this

hypothesis would suggest that the top income shares actually were increasing in the 1990s but the CPS data are unable to observe this change.

Another possible explanation is that a greater increase in the use of tax-deferred savings accounts (401k plans, Keogh plans, and IRA tax shelters) by individual in top income groups outside the top 1% may explain part of the rise in the income share of the top 1% in the Piketty-Saez series for the late 1990s. Wolff (1998) finds that pension assets are much more important to individuals outside the top 1% of the wealth distribution. However, Porterba, Venti, and Wise (2004) show that the ratio of all pensions, including defined benefit and defined contributions to payroll, was steady through at least 1999. Thus, if this explanation explains the discrepancy, it is possible that it is because income previously received as defined benefits, missed by both the IRS and CPS data prior to retirement, are now received as defined contribution income, which only the IRS data miss. As a result, the CPS data could artificially observe slower inequality growth as individuals shift from unobserved to observed pension income. The IRS data, in contrast, would overstate the levels of top income shares by excluding this source of income primarily received lower in the distribution but would be accurate in the trends.

Each of these explanations for the diverging trends is plausible but difficult to investigate further with either data set. The view that the CPS did an increasingly poorer job of capturing top incomes in the late 1990s is also plausible. But if this is the explanation, the timing of the differences is curious. After its redesign in 1993, the CPS was better able to capture top incomes, as evidenced by the artificial jump in inequality in both of our CPS series between 1992 and 1993. Moreover, the prevalence of censoring during

TABLE 2.—AVERAGE ANNUAL PERCENTAGE CHANGE IN INCOME INEQUALITY USING THREE INEQUALITY MEASURES, BY SUBPERIOD BETWEEN 1967 AND 2006, ADJUSTING FOR MEASUREMENT CHANGES IN 1992–1993 IN THE CPS DATA

Subperiod	CPS Post-HH			CPS Pre-TU		
	Gini	Share of Top 1%	Share of Top 10%	Gini	Share of Top 1%	Share of Top 10%
1967–1980	0.1	–0.5	–0.2	0.4	0.2	0.5
1980–1986	1.2	1.7	1.1	0.7	1.9	1.1
1986–1988	0.6	3.2	0.9	–0.1	2.0	0.5
1988–1992	0.4	0.0	0.5	0.9	0.8	1.0
1992–1993 ^a	–0.8	–4.9	–0.8	–0.8	–4.9	–0.8
1993–2000	0.2	1.6	0.7	0.0	1.5	0.4
2000–2006	0.6	1.3	0.5	0.5	1.4	0.7
1967–2006 ^b	0.4	0.6	0.4	0.4	1.0	0.7

For sources, see figure 1.

^aFollowing the procedure in figure 4, the CPS series is adjusted upward prior to 1993 to reflect the systematic undercounting of income from top-income households prior to the 1993 CPS redesign. The change between 1992 and 1993 is reported as the corresponding change observed by Piketty and Saez (2003) using IRS records. Since the Gini coefficient cannot be calculated in the IRS data, the 1992–1993 change assumed for the Gini coefficient matches that in the IRS tax return data for the top 10% income share. From other years, this appears to be the closest approximation available in the IRS data.

^bFollowing the procedure in figure 4, the CPS series is adjusted upward prior to 1993 to reflect the systematic undercounting of income from top-income households prior to the 1993 CPS redesign, thus suppressing the 1992–1993 blip and replacing it with the corresponding change observed by Piketty and Saez (2003) using IRS records.

this period—after the internal data top codes were increased—was lower than it was in the mid-1980s or in the early twenty-first century.¹⁰ So the CPS design changes should have increased the survey's ability to accurately observe top incomes during this period.

How might future research proceed to investigate these divergences further? Since the two data sets are remarkably similar below the 99th percentile and diverge in the 1990s only for the top 1%, researchers particularly concerned with this additional reconciliation of the data sets for the late 1990s should focus on elements of one or both data sets that effect trends differently during this period alone.

For researchers particularly interested in the top 1% income share in the late 1990s, the Survey of Consumer Finance (SCF) may be a fruitful source for comparisons. Wolff and Zacharias (2009) compare SCF estimates of top income shares to those of Piketty and Saez and find similar levels for the share of the top 1% in recent years, although they observe more of the rise coming prior to 1994 than Piketty and Saez do. Kennickell (2009) compares SCF estimates to Piketty and Saez's estimates for income including capital gains and finds a top 1% income share in 2006 that is less than 1 percentage point below that reported by Piketty and Saez, along with similar, but slightly smaller, trends in the top 1% income share since 1994. Because the SCF produces top income share estimates that are in line with those from the CPS and IRS data, researchers interested in more fully understanding the 1993 to 2000 discrepancy between the data sets may be able to gain insight into the precise causes through a careful analysis that includes all three of these data sets.

VI. Income Inequality Trends According to Gini Coefficients

Thus far we have explored the ability of CPS data to capture trends in the share of pretax, pretransfer income going

¹⁰ See Larrimore et al. (2008) for detailed information about the prevalence of censoring in the internal CPS data year by year.

to top tax units in the IRS tax record data as measured by Piketty and Saez. But inequality trends can also be influenced by the choice of inequality index. It is less clear, though, whether this choice has a practical impact on recent inequality trends in the United States. From country-level time-series cross-section data, Leigh (2007) concludes that top income shares track other inequality measures reasonably well. However, to our knowledge, no previous study has performed a comparison of inequality trends using both the Gini coefficient and top income shares using a long run of comparable unit record data from the same country.

Since a top income share is the only inequality measure that can be readily derived from IRS tax record data, we focus this analysis on the CPS data. Using the two CPS-based series, we compare the observed growth in income inequality using the Gini coefficient to the trend in the income share of the top 1% and the top 10% of the population. By using the same sample to compare results for these three inequality measures, we can determine the extent to which the choice of inequality measures influences the observed trends in income inequality.

Table 2 shows the average annual percentage increases using these three income inequality measures in the CPS data for the seven subperiods since 1967 and for the entire forty-year period, suppressing the artificial increase from the 1992–1993 redesign.¹¹ Using either CPS-based income series, the two top-income-share series exhibit faster inequality growth than the Gini series when considering the entire forty-year period. When considering the subperiods, the pattern is mixed, with the top 1%'s income share exhibiting higher growth than the Gini coefficient in some periods (1980–1988, 1993–2000, and 2000–2006) and slower growth in others (1967–1980 and 1988–1992). During the

¹¹ For 1992–1993, since no Gini index is available in the IRS data when approximating the amount of the inequality increase that is real and the amount attributable to the redesign, it is assumed that the actual Gini increase matches the increase seen for the top 10% income share. This one-year assumption is relevant only for the average change over the entire forty-year period and the choice of this, or another reasonable assumption, should not greatly change those results.

period of greatest disagreement between the two literatures—from the early 1990s through the 2000s, when the IRS-based literature has observed much larger increases in income inequality—this difference is quite large. Using the CPS-Pre-TU series, the growth in inequality as measured by the top 1%’s income share grew approximately 1.5% per year from 1993 through 2006. This compares to an average annual growth of just 0.3% per year in the Gini coefficient. (The growth in the top 10%’s income share is much closer to that of the Gini.)

These results also help explain why researchers examining top income shares using IRS tax records have found continued inequality growth through the 1990s, while researchers examining Gini coefficients using CPS data have not. We previously observed some differences in inequality trends between the two data sets during this period even using the same inequality measure. However, table 2 shows that differences in the inequality trends observed in these two literatures also stem from differences in the inequality index used.

Since there are discrepancies in the top 1% income shares across the two data sets in the 1990s, however, this complicates the analysis for researchers who prefer the IRS-based top 1% results but also wish to use the Gini coefficient to measure inequality. But since we have demonstrated that the IRS and CPS data are consistent up through the 99th percentile, it is possible to incorporate one’s preferred top 1% series by using the Gini from the bottom 99% of the distribution from the CPS data along with information about the top 1% of the distribution from IRS data. This type of approach is demonstrated by Atkinson et al. (2011). For researchers interested in combining the data sets in this way, Gini coefficients for the bottom 99% of the population estimated using our CPS-Pre-TU and CPS-Post-HH series are provided in table C1, together with estimates for the population as a whole.

VII. Summary and Conclusion

We analyze trends in top income shares in the United States over four decades (1967–2006), with the goal of reconciling estimates derived from the CPS with those reported by Piketty and Saez (2003) and derived from IRS tax return data. Our CPS-based estimates (based on income measures that exclude capital gains) draw on the internal data used by the Census Bureau to produce its official income statistics, a much better source for examining income distribution trends than the CPS public use data because the prevalence of top coding is substantially smaller.

When applying a Piketty-Saez-type definition of the income distribution to CPS data (the CPS-Pre-TU series), we derive estimates of top income shares that are remarkably similar in terms of both levels and trends to those reported by Piketty and Saez (2003, 2008) for both the p90–p95 and p95–p99 groups. The shares grew in the

1980s and then slowed starting in the early 1990s. For the top 1%, our CPS-Pre-TU series provides slightly lower share estimates than the Piketty-Saez series does, but with the exception of the period 1993 to 2000, the trends in the series are similar. Thus, we conclude that the differences in inequality trends observed by researchers using these two data sources are not primarily due to deficiencies in either data source but rather to the traditions of income inequality measurement used in the two literatures.

To explore this possibility further, we also measure income inequality using the Gini coefficient in the March CPS data, and compare results to those using top income shares. When using identical data, source of income, and income receiving units but different inequality measures, we found that the growth in the income share of the top 1% of the population substantially outpaced measured inequality using the Gini coefficient (see table 2). Thus, we conclude that at least part of the differing views in the two literatures about recent trends in income inequality can be attributed to differences in the literatures’ measures of income inequality. Specifically, while the income divergence between the very top income holders and the rest of society was growing in the 1990s, the growth in income inequality across the entire distribution occurred at a more moderate pace.

When we use the same measure of income inequality (the income share of the top 1%) and similar income definitions (pretransfer, tax unit income excluding capital gains) with the CPS data, we are, for the most part, able to reproduce the same levels and trends Piketty and Saez find using the IRS tax record data. The only divergence in observed income inequality unexplained by a known deficiency in either or both data sets occurs over the period 1993 to 2000. It is possible that in this period of rapid economic growth, the CPS was unable to capture the rise in pretax, pretransfer income of the very richest people or that one or both data sets were limited in their analysis of income trends due to income that is outside the scope of their collection procedures. But despite this limitation, users of both CPS and of IRS tax return data should be comforted by our finding that for most groups at the top and for most of the past four decades, the differences in estimates from the two data sources are minor.

Given that we find that trends in top income shares derived from CPS data are broadly consistent with trends estimated from IRS tax return data and since the CPS includes many sociodemographic variables that are not available in tax return data, CPS survey data are a useful source for the study of top income shares. Nevertheless, the trend in the share of the top 1% estimated from CPS data is below the trend estimated from tax return data, and particularly so if the tax data income measure includes capital gains, stock options, and bonuses. Information about these sources is not collected by the CPS, and yet they are important for individuals at the top of the distribution. Thus, the way forward may be to use the CPS and IRS tax return data

in combination, drawing on the CPS for sociodemographic variables and household composition and the IRS data for income variables that cannot be obtained from the CPS. We propose that the Census Bureau and the IRS work together to find ways to match IRS administrative record data to CPS responses because linked data would provide an opportunity to draw on the comparative advantages of each data set. Record linkage may be more feasible than adding questions to the CPS as it need not substantially increase respondent burden.

APPENDIX A

Sensitivity Analysis: Pareto-Based Imputation and No Imputation (Unadjusted Internal CPS Data)

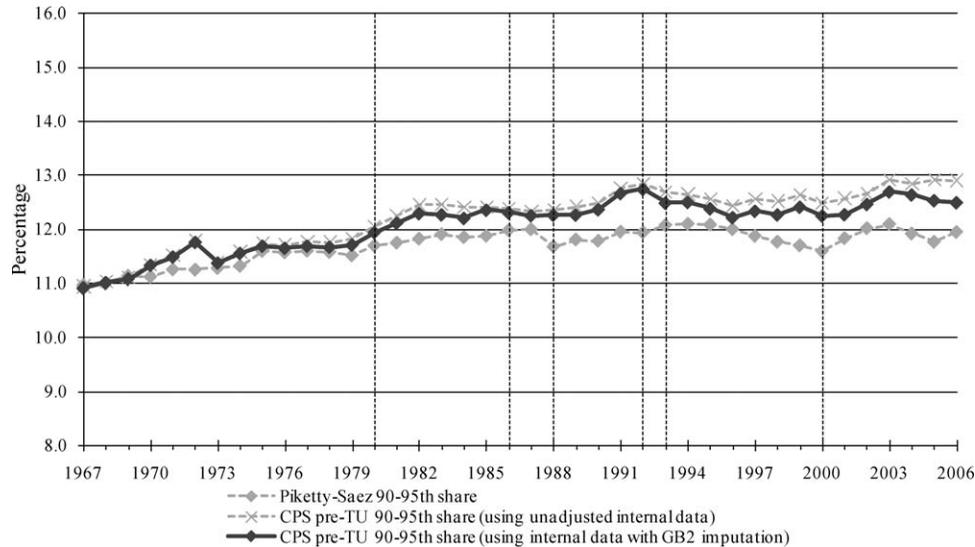

Imputation of some kind is necessary when one wishes to calculate income inequality for the entire income distribution including top-coded observations, and imputation has therefore been commonly used in both the CPS-based inequality literature and the IRS-based inequality literature. To account for censoring in the internal CPS data (albeit of limited extent), we used the multiple imputation (MI) approach described in the main text. To investigate the potential sensitivity of our results to this choice, we also considered the implications of, first, using imputations based on the assumption that top incomes follow the Pareto distribution and, second, using no imputation at all, that is, using unadjusted internal CPS data. To investigate the Pareto approach, we computed the beta coefficients implied by our GB2-based multiply imputed data and compared these to the beta coefficients from Piketty and Saez's (2008) results. For any threshold, y , the Pareto beta coefficient can be calculated as $\beta = \bar{y}(y)/y$, where $\bar{y}(y)$ is the mean income above the income threshold y . If the Pareto distribution correctly describes the distribution above a particular threshold y° , then estimates of β should be the same if recomputed using any threshold $y > y^\circ$. For Pareto-based imputation to be robust, we would hope to observe little variation in the estimates of β with different top-income thresholds. However, the values of beta derived from both Piketty and Saez's and our data sets depend on the threshold chosen, and so we report values calculated for three thresholds (p90, p95, and p99). We derive them from our multiply imputed CPS data for each year using our CPS Pre-TU income definition and compare them with the beta coefficients derived from Piketty and Saez's IRS tax record data using the same thresholds. The estimates are plotted in figure A1.

FIGURE A1.—PARETO BETA COEFFICIENTS DERIVED FROM GB2-BASED MULTIPLY IMPUTED CPS DATA AND IRS TAX DATA, BY TOP INCOME THRESHOLD, 1967–2006

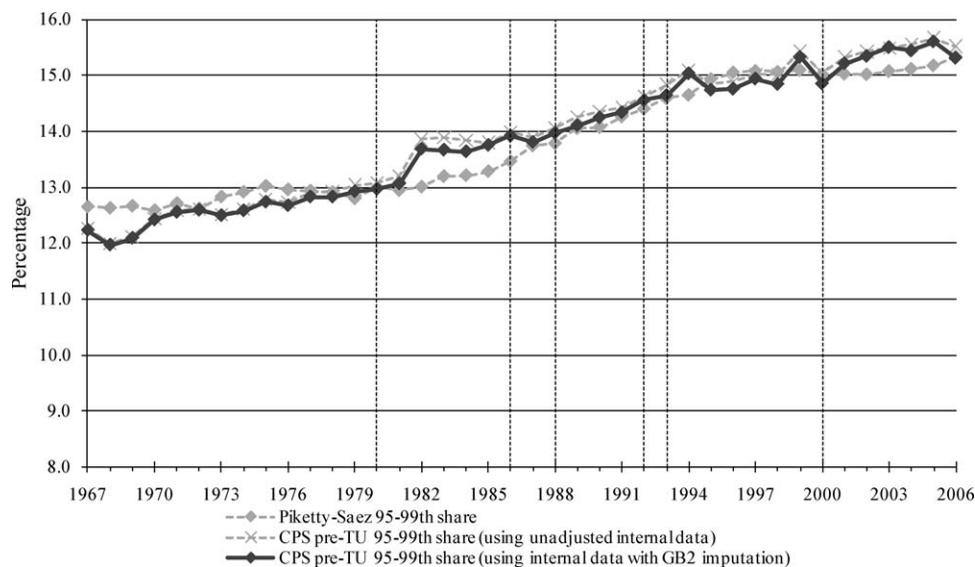

Sources: The Piketty-Saez series is taken from Piketty and Saez (2003, 2008). It refers to the distribution of pretax, pretransfer income among tax units. The CPS-based series were derived by the authors from CPS internal data. The CPS-Pre-TU series with the GB2 imputation matches the CPS-Pre-TU series from the main text, using our GB2 imputation to derive censored incomes in the internal data. The CPS-Pre-TU series using unadjusted internal data uses the unadjusted internal data as is. See appendix A and the main text for further details.

FIGURE A2.—INTERNAL CPS DATA ESTIMATES OF THE SHARE OF TOTAL INCOME HELD BY UNITS WITH INCOMES BETWEEN THE 90TH AND 95TH PERCENTILES, WITH AND WITHOUT GB2-BASED MULTIPLY IMPUTED IMPUTATIONS FOR CENSORED OBSERVATIONS, 1967–2006

See the note to figure A1 for sources.

FIGURE A3.—INTERNAL CPS DATA ESTIMATES OF THE SHARE OF TOTAL INCOME HELD BY UNITS WITH INCOMES BETWEEN THE 95TH AND 99TH PERCENTILES, WITH AND WITHOUT GB2-BASED MULTIPLY IMPUTED IMPUTATIONS FOR CENSORED OBSERVATIONS, 1967–2006

See the note to figure A1 for sources.

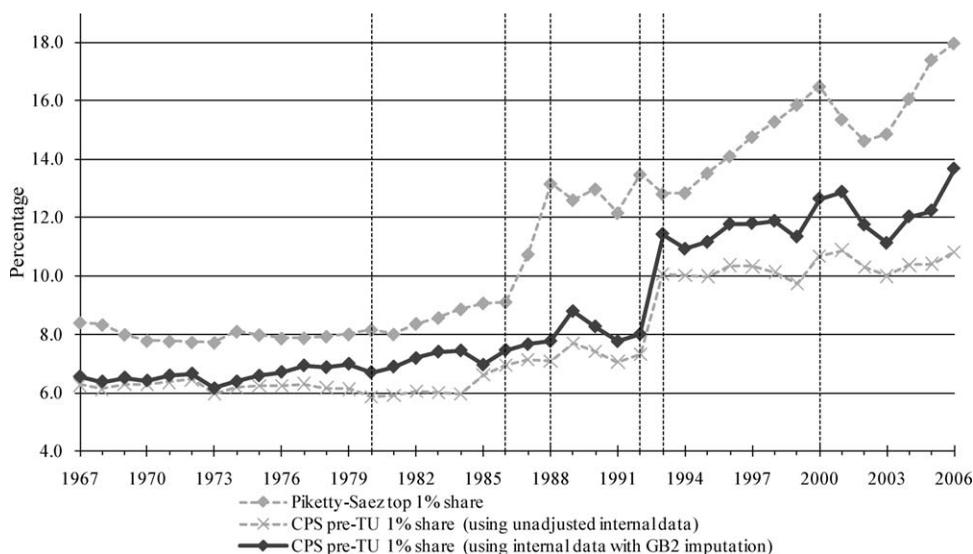

When each of the three thresholds is used, the beta coefficients implied from our GB2 estimation are somewhat lower than those in the IRS data. Since a higher beta coefficient indicates greater concentration in the upper tail of the distribution, had we assumed that top incomes fit a Pareto distribution characterized by the parameters implied by the IRS data, the top 1% income shares would be slightly greater than those shown in the main body of the paper and would likely be even closer to those reported by Piketty and Saez (2003).

We also undertook all our calculations of top income shares from unadjusted internal CPS data used as is, without imputations for censored values. Figures A2 through A4 provide the top income shares using the pretax, pretransfer tax unit income definition estimated from both the unadjusted internal CPS data series and our CPS data series, which includes GB2-based multiple imputations for top-coded observations.

For the p90–p95 income group and the p95–p99 income group, the levels and trends in income shares derived from the unadjusted CPS data closely match those from the MI series, and both are close to the levels and trends shown by Piketty and Saez (2003) using IRS tax records. This is not unexpected, as less than 1% of individuals lived in a household in which some source of income was censored in the internal data: censoring primarily affects those in the very top income group.

For the income share of the top 1%, using the unadjusted CPS data rather than the MI data results in a lower level of measured income inequality and a slightly lower income inequality growth. The general patterns of inequality increases are similar, however, with the share of the 1% increasing at a pace similar to that shown by Piketty and Saez in the 1980s (although the unadjusted internal data observe the increase later in the 1980s than the other two series). As with the MI series, the rate of

FIGURE A4.—INTERNAL CPS DATA ESTIMATES OF THE SHARE OF TOTAL INCOME HELD BY THE TOP 1% OF UNITS, WITH AND WITHOUT GB2-BASED MULTIPLY IMPUTED IMPUTATIONS FOR CENSORED OBSERVATIONS, 1967–2006

See the note to figure A1.

increase in the share of the top 1% then slows in the 1990s compared to that reported by Piketty and Saez before showing similar patterns again in the early twenty-first century.

Thus, our main findings hold even if no imputations are made for the small number of observations censored in the internal CPS data. When differences in income definitions and inequality measures are controlled for, estimates using CPS and IRS data are consistent for almost all of the past forty years with the exception of the mid to late 1990s.

APPENDIX B

Sources of Income: Unadjusted Internal CPS Data versus Piketty-Saez Data

Having established that in general, the share of income in March CPS data going to the top 10% of the distribution closely matches that found in IRS tax record data by Piketty and Saez (2007), we also seek to understand how the sources of income compare for these individuals. When doing so, it is necessary to use the unadjusted internal data rather than the data based on our GB2-based multiple imputation (MI) procedure. This is because the MI procedure is used to impute the total income of right-censored observations and, hence, income sources cannot be identified for observations with imputed values. (It is infeasible to impute each income source separately and then aggregate across income sources. To do so, the imputation model would have to characterize cross-source correlations as well as the marginal distributions, the number of which would increase substantially in any case.)

By using the unadjusted internal CPS data rather than the MI data, we are unable to observe the actual incomes or their sources for observations

with censored income. But since many individuals in the top 1% of the income distribution have top-coded data, we provide meaningful income source information only for the p90–p95 and p95–p99 income groups, where censoring is less prevalent. The sources of income for the p90–p95 and p95–p99 are provided in tables B1 and B2, and despite the limitation of the reliability of the source-level breakdown for the top 1%, the sources of income for the top 1% are provided in table B3.

As illustrated in table B1, the sources of income are similar for the p90–p95 income groups in the CPS and IRS data. The percentage of income among members of this group received from wages ranges from 85.1% to 89.3% of income when using the CPS-Pre-TU data, compared to a range of 86.9% to 91.6% of income when using the IRS tax records data. Although there are some year-to-year fluctuations in the income received from wages, the level is remarkably stable in both the IRS and CPS data over the forty-year period.

Among the p95–p99 income group, the income shares are also as similar, with the share of income received from wages ranging from 74.8% to 85.7% of income in the CPS data and from 73.3% to 84.4% of income in the IRS tax records data (see table B2). There are only five years (1983, 1996, 1998, 1999) where the difference in the share of income received from wages is greater than 4% in the two data sets. Additionally, both data sets show increases in the portion of wages from income of approximately 7.5% over the forty-year period while the income from entrepreneurial activities declined. The only substantial difference between the series is that the IRS tax records data indicate that the portion of income from assets declined from 1967, whereas the CPS data suggest that asset income increased in importance to these high-income individuals. In general, however, not only do the IRS and CPS data closely match the share of income received by top earners in the income distribution, but they also provide similar results for the sources of that income.

TABLE B1.—INCOME COMPOSITION BY SOURCE FOR TAX UNITS WITH INCOMES BETWEEN THE 90TH AND 95TH PERCENTILES OF THE INCOME DISTRIBUTION, 1967–2006

Year	CPS Pre-TU (Unadjusted)			Piketty-Saez		
	Wage	Entrepreneurial	Asset	Wage	Entrepreneurial	Asset
1967	86.3	10.3	3.3	88.2	7.3	4.6

1986	86.9	6.4	6.6	90.1	3.8	6.0
1987	86.5	8.0	5.4	90.1	4.3	5.6
1988	86.7	6.9	6.4	89.4	4.9	5.8
1989	85.7	7.8	6.5	88.6	4.9	6.5
1990	85.7	7.5	6.8	88.7	4.7	6.6
1991	86.3	7.8	5.9	89.4	4.7	5.9
1992	87.0	7.4	5.7	90.9	4.3	4.8
1993	88.2	6.3	5.6	90.9	5.0	4.2
1994	89.2	5.6	5.2	91.1	5.0	3.9
1995	88.4	5.6	6.0	91.6	4.5	3.9
1996	86.4	6.4	7.2	90.8	4.7	4.6
1997	85.7	6.2	8.2	91.0	4.8	4.2
1998	86.1	6.1	7.8	91.1	4.9	4.0
1999	85.4	6.4	8.2	90.6	5.5	3.9
2000	87.4	5.7	6.9	89.7	5.6	4.7
2001	87.8	5.8	6.5	91.2	5.0	3.8
2002	89.2	5.5	5.3	89.9	6.2	4.0
2003	88.5	5.4	6.0	90.1	6.3	3.6
2004	88.9	5.3	5.8	89.4	6.8	3.8
2005	88.5	5.0	6.5	88.1	7.5	4.4
2006	86.9	6.1	7.1	88.2	6.8	5.1

The Piketty-Saez series is calculated from Piketty and Saez (2007, 2008). The CPS-Pre-TU series using unadjusted internal data uses the unadjusted internal data as is. See Appendix A and the main text for further details. Entrepreneurial income includes self-employment and farm income. Asset income includes interest from interest, dividends, and rents. For comparability with the source decomposition results presented in Piketty and Saez (2007), income from other sources is excluded, and the sum of incomes from wages, entrepreneurial activities, and asset income is scaled to sum to 100%. Other forms of income represent less than 4% of income in all years.

TABLE B2.—INCOME COMPOSITION BY SOURCE FOR TAX UNITS WITH INCOMES BETWEEN THE 95TH AND 99TH PERCENTILES OF THE INCOME DISTRIBUTION, 1967–2006

Year	CPS Pre-TU (Unadjusted)			Piketty-Saez

1995	80.2	10.8	9.0	59.2	27.3	13.5
1996	80.7	11.0	8.3	59.7	27.0	13.3
1997	77.7	12.6	9.7	60.3	26.7	13.0
1998	77.3	14.2	8.5	61.1	26.6	12.3
1999	81.7	8.2	10.1	62.1	26.1	11.8
2000	82.0	10.6	7.3	63.0	24.7	12.3
2001	82.9	10.1	7.1	61.7	26.5	11.8
2002	86.9	8.3	4.8	61.2	27.4	11.4
2003	83.5	11.0	5.6	60.2	27.7	12.1
2004	84.7	9.0	6.2	58.4	28.4	13.2
2005	81.8	12.6	5.7	54.8	30.9	14.4
2006	82.0	10.8	7.2	53.5	30.1	16.4

See the note to table B1. Because censoring threshold changes vary by income source, the sources of income in the unadjusted CPS data are particularly sensitive to changes in the top code thresholds and, unlike results in the main text of the paper, these results are not adjusted using the GB2-based multiple imputation procedure. Thus, while income composition results are provided for the top 1% for completeness and as a reference for the reader, we discourage overanalyzing the composition of the top 1% due to these censoring concerns.

APPENDIX C

Supplemental Information on Income Inequality among the Bottom 99% of the Income Distribution

TABLE C1.—GINI COEFFICIENTS FOR THE ENTIRE POPULATION AND THE BOTTOM 99% OF THE INCOME DISTRIBUTION USING THE TWO CPS-BASED INCOME DEFINITIONS, 1967–2006

	Gini Coefficients Entire Population		Gini Coefficients Excluding the Top 1%	
	CPS-Post-HH	CPS-Pre-TU	CPS-Post-HH	CPS-Pre-TU
1967	0.365	0.479	0.339	0.457
1968	0.353	0.474	0.329	0.453
1969	0.354	0.479	0.330	0.458
1970	0.358	0.488	0.335	0.468

2006	0.457	0.588	0.404	0.540

Authors' calculations using Internal March CPS data. No adjustment is made for the blip in the CPS data between 1992 and 1993. A corresponding series adjusting for the 1992–1993 blip using the methods described in the main text of the paper is available on request from the authors.
