ABSTRACT

We use the observed anisotropic clustering of galaxies in the Baryon Oscillation Spectroscopic Survey Data Release 11 CMASS sample to measure the linear growth rate of structure, the Hubble expansion rate and the comoving distance scale. Our sample covers 8498 deg2 and encloses an effective volume of 6 Gpc3 at an effective redshift of $\bar{z} = 0.57$. We find $f_{\sigma_8} = 0.441 \pm 0.044$, $H = 93.1 \pm 3.0\ km\ s^{-1}\ Mpc^{-1}$ and $D_A = 1380 \pm 23\ Mpc$ when fitting the growth and expansion rate simultaneously. When we fix the background expansion to the...
1 INTRODUCTION

Galaxies map the distribution of the underlying dark matter field and provide invaluable information about both the nature of dark energy (DE) and properties of gravity (see e.g. Weinberg et al. 2013). The shape of the two-point correlation function of the observed galaxy field, or of its Fourier-transform – the power-spectrum, contains features such as baryon acoustic oscillations (BAO) and the turnover marking the transition between radiation-dominated and matter-dominated evolutionary phases (Eisenstein & Hu 1998; Meiksin, White & Peacock 1999). These features can be used to place tight constraints on relative abundances of different energy-density components of the Universe (radiation $\rho_r$, dark matter $\rho_m$, baryonic matter $\rho_b$ and DE $\rho_{DE}$). Presently, these ratios are measured to much higher accuracy in the cosmic microwave background (CMB; Planck Collaboration 2013). Therefore, for most cosmological models these features provide most information when used as a standard ruler.

If the Universe is statistically isotropic and homogeneous on large scales, the correlation function and power spectrum should likewise be rotationally invariant. The observed two-point statistics instead exhibit a strong anisotropy with respect to the line-of-sight (LOS) direction. Two effects are responsible for this apparent anisotropy: the redshift-space distortions (RSD; Kaiser 1987) and the Alcock–Paczynski effect (AP; Alcock & Paczynski 1979).

The RSD arise in maps made from galaxies if distances are determined from measured redshifts assuming that they are only caused by the Hubble flow. Because of gravitational growth, the galaxies tend to infall towards high-density regions and flow away from low-density regions, such that the clustering is enhanced in the LOS direction compared to the perpendicular direction. The observed redshifts thus have a component aligned with these flows. On large scales where gravitational growth is linear, measuring the relative clustering in both LOS and transverse directions leads to a measurement of the logarithmic growth rate of structure

$$ f(a)\sigma_8(a) = \sigma_8(a = 1) \frac{dG(a)}{d\ln a}, \tag{1} $$

where $a$ is a scalefactor, $\sigma_8(a)$ is a measure of the amplitude of the matter power spectrum and $G(a)$ is the linear growth function normalized such that $G(a = 1) = 1$ (see Hamilton 1998 for a review of RSD).

The magnitude of the large-scale velocity field traced by galaxies depends on the nature of gravitational interactions, and measured values of $f\sigma_8$ can be used to constrain models of gravity (see e.g. Guzzo et al. 2008). Galaxy clustering data measures the growth at low redshifts. Combining this information with the accurate estimates of the amplitude of matter perturbations at $z \sim 1000$ provided by CMB allows for extremely strong constraints for deviations from the predictions of general relativity (GR) since even small changes in the growth of structure accumulate to a large offset over cosmic time (for recent GR constraints see e.g. Zhao et al. 2012; Rapetti et al. 2013; Samushia et al. 2013; Sanchez et al. 2013a; Simpson et al. 2013).

Anisotropies are also observed due to the AP effect, which stems from the fact that we need to convert observed angular positions and redshifts of galaxies to physical coordinates in order to measure clustering statistics. If the fiducial cosmology used for this mapping is different from the true cosmology, this will induce anisotropies in the measured clustering pattern even in the absence of RSD. Angular distortions are sensitive to the offset in the angular distance $D_A(z)$ and distortions in the LOS direction depend on the offset in $H(z)$. Measuring the AP effect provides accurate estimates of the angular distance and Hubble parameter and can be used to constrain properties of DE (see e.g. Eisenstein, Seo & White 2007). Measurements of both angular and radial projected scales are usually reported in terms of the volume-averaged distance

$$ D_V = \left(1 + z\right)^2 c^2 D_A^2 H^{-1/3}, \tag{2} $$

and the AP parameter

$$ F = \frac{1 + z}{c} D_A H. \tag{3} $$

In the absence of RSD, the measured correlation function monopole would be sensitive mostly to isotropic scale dilution through $D_A$ and the quadrupole to anisotropic scale dilution through $F$. Most of the information on $D_V$ usually comes from the most pronounced feature in the correlation function – the position of the BAO peak in the monopole. It is therefore convenient to report results in terms of $D_V/r_s$, where $r_s$ is the sound horizon at the drag epoch which sets the BAO scale (for a review of BAO and AP see e.g. Bassett & Hlozek 2010).

The RSD and AP are partially degenerate but have a different scale dependence which makes their simultaneous measurement possible (Ballinger, Peacock & Heavens 1996). Specifying cosmological models of background expansion or gravity helps to further break this degeneracy (e.g. Samushia et al. 2011). Measuring correlation function in different fiducial cosmological models and fitting the RSD signal in each can help to reduce the degeneracy as well (Marulli et al. 2012).
The RSD signal within the correlation function is difficult to model because of the significant contribution from non-linear effects and higher order contributions from galaxy bias. A number of recent studies have shown that many current RSD models result in biased estimates of the growth rate (see e.g. Bianchi et al. 2012; de la Torre & Guzzo 2012; Gil-Marin et al. 2012). In our work, we use the ‘streaming model’-based approach developed in Reid & White (2011) that has been demonstrated to fit the monopole and quadrupole of the galaxy correlation function with better than percent level precision to scales above 25h⁻¹ Mpc, for galaxies with bias of b ≃ 2.¹

Many distance-scale and RSD measurements have previously been made using spectroscopic survey data. Recent highlights include the BAO measurements from the 6dF Galaxy Redshift Survey (6dFGRS; Beutler et al. 2011), Sloan Digital Sky Survey II (SDSS-II; Padmanabhan et al. 2012), SDSS-III Baryon Oscillation Spectroscopic Survey (BOSS) Data Release 9 sample (DR9; Anderson et al. 2012), WiggleZ survey (Blake et al. 2011b) and SDSS-III BOSS DR10 and DR11 samples (Anderson et al. 2013). The RSD signal has been measured in the 6dFGRS (Beutler et al. 2012), the SDSS-II survey (Samushia, Percival & Raccanelli 2012), the SDSS-III BOSS DR9 data (Reid et al. 2012) and VIMOS Public Extragalactic Redshift Survey (VIPERS; de la Torre et al. 2013). Simultaneous fits to RSD and AP parameters have been performed for the WiggleZ survey (Blake et al. 2012), SDSS-II data (Chuang & Wang 2013) and SDSS-III BOSS DR9 data (Reid et al. 2012).

The analysis presented in this paper builds upon that of Reid et al. (2012), who measured the RSD and AP simultaneously in the BOSS CMASS DR9 sample, achieving a 15 per cent measurement of growth, 2.8 per cent measurement of angular diameter distance and 4.6 per cent measurement of the expansion rate at z = 0.57. Using these estimates Samushia et al. (2013) derived strong constraints on modified theories of gravity (MG) and DE model parameters. In this paper, we perform a similar analysis on the CMASS DR11 sample, which covers roughly three times the volume of DR9.

This paper is organized as follows. In Section 2, we describe the data used in the analysis. Section 3 explains how the two-dimensional correlation function is estimated from the data. Section 4 shows how we derive the estimates of the covariance matrix for our measurements. In Section 5, we describe the theoretical model used to fit the data. Section 6 presents and discusses our main results—the estimates of growth rate, distance-redshift relationship and the expansion rate from the measurements. Section 7 uses these estimates to constrain parameters in the Λ cold dark matter (ΛCDM) model assuming GR (ΛCDM-GR) and possible deviations from this standard model. We conclude and discuss our results in Section 8.

Our measurements require the adoption of a cosmological model in order to convert angles and redshifts into comoving distances. As in Anderson et al. (2013), we adopt a spatially flat ΛCDM cosmology with Ω_m = 0.274 and h = 0.7 for this purpose. For ease of comparison across analyses, we follow Anderson et al. (2013) and also report our distance constraints relative to a model with Ω_m = 0.274, h = 0.7 and Ω_bh² = 0.0224, for which the BAO scale r_d = 149.31 Mpc.

Figure 1. The number density of CMASS DR11 galaxies in redshift bins of Δz = 0.01 in northern and southern Galactic hemispheres, computed assuming our fiducial cosmology.

2 THE DATA

The SDSS-III project (Eisenstein et al. 2011) uses a dedicated 2.5 m Sloan telescope (Gunn et al. 2013) to perform spectroscopic follow-up of targets selected from images made using a now-retired drift-scanning mosaic CCD camera (Gunn et al. 2006) that imaged the sky in five photometric bands (Fukugita et al. 1996) to a limiting magnitude of r ≃ 22.5. The BOSS (Dawson et al. 2013) is part of SDSS-III that will measure spectra for 1.5 million galaxies and 160,000 quasars over a quarter of the sky.

We use the DR11 CMASS sample of galaxies (Bolton et al. 2012; Anderson et al. 2013; Sme et al. 2013). This lies in the redshift range of 0.43 < z < 0.70 and consists of 690,826 galaxies covering 8498 square degrees (effective volume of 6 Gpc³). Most galaxies in the sample belong to the red sequence. About 25 per cent of them, however, would be classified as ‘blue’ according to traditional SDSS rest-frame colour cuts (see e.g. Strateva et al. 2001). Ross et al. (2014) showed that there is no detectable colour dependence of distance-scale and growth-rate measurements in DR10 sample.

The number density is of the order of 10⁻⁴ peaking at n_g ≃ 4 × 10⁻⁴ h³ Mpc⁻³.

3 THE MEASUREMENTS

We measure the correlation function of galaxies in the CMASS sample defined as the ensemble average of the product of overdensities in the galaxy field separated by a certain distance r

\[ \xi(r) \equiv \langle \delta_g(r') \delta_g(r + r') \rangle. \]  

(4)

The overdensity as a function of r is given by

\[ \delta_g(r) = \frac{n_g(r) - \bar{n}_g}{\bar{n}_g}, \]  

(5)

where \( \bar{n}_g(r) \) is the expected average density of galaxies at a position \( r \), and \( n_g(r) \) is an observed number density.

We estimate the correlation function using the Landy–Szalay minimum-variance estimator (Landy & Szalay 1993)

\[ \hat{\xi}(\Delta r) = \frac{DD(\Delta r) - 2DR(\Delta r) + RR(\Delta r)}{RR(\Delta r)}, \]  

(6)
BOSS anisotropic clustering

Figure 2. The two-dimensional correlation function of DR11 sample measured in bins of $1\,h^{-1} \times 1\,h^{-1}\,\text{Mpc}^2$. We use first two Legendre multipoles of the correlation function in our study rather than the two-dimensional correlation function displayed here.

where $DD(\Delta r_i)$ is the weighted number of galaxy pairs whose separation falls within the $\Delta r_i$ bin, $RR(\Delta r_i)$ is number of similar pairs in the random catalogue and $DR(\Delta r_i)$ is the number of cross-pairs between the galaxies and the objects in the random catalogue.

Fig. 2 shows the two-dimensional correlation function of DR11 sample measured in bins of $1\,h^{-1} \times 1\,h^{-1}\,\text{Mpc}^2$. Both the ‘BAO ridge’ (a ring of local maxima at approximately $100\,h^{-1}\,\text{Mpc}$) and the RSD signal (LOS ‘squashing’ of the correlation function) are detectable by eye.

The random catalogue is constructed by populating the volume covered by galaxies with random points with zero correlation. We use a random catalogue that has 50 times the density of galaxies to eliminate extra uncertainty associated with the shot noise in the random catalogue.

We weight each galaxy in the catalogue with three independent weights. First is the Feldman–Kaiser–Peacock (FKP; Feldman, Kaiser & Peacock 1994) weight $w_{\text{FKP}} = 1/(1 + \bar{n}(z)20000)$. This approach downweights galaxies in high-density regions, achieving a balance between cosmic variance and shot-noise errors. The second weight $w_{\text{sys}} = w_{\text{star}}w_{\text{sec}}$ accounts for the systematic effects associated with both the varying stellar density ($w_{\text{star}}$; Ross et al. 2012) and seeing variations in the imaging catalogue used for targeting ($w_{\text{sec}}$; Anderson et al. 2013). The third weight corrects for the missed galaxies due to fibre collisions and redshift failures using the algorithm described in Anderson et al. (2012). The former is caused by the finite size of fibres that makes simultaneous measurement of spectra of two galaxies with small angular separation impossible. To correct for both of these effects, we upweight each galaxy by the number of its lost neighbours and the resulting weight is $(w_{\text{cp}} + w_{\text{zf}} - 1)$. Since these effects are statistically independent, the total weight is a product of three $w_{\text{tot}} = w_{\text{FKP}}w_{\text{sys}}(w_{\text{cp}} + w_{\text{zf}} - 1)$. The weight of the pair is the product of individual weights for two galaxies. Since the stellar and close-pair effects are absent in the random catalogue, we apply only the FKP weight to them.

The observed correlation function is a function of two variables: we use $r$, the distance between galaxies, and $\mu$, the cosine of the angle between their connecting vector and the LOS. The optimal choice of binning for the correlation function measurements depends on two competing effects. Using small bin size retains more information, but since we estimate covariance matrices by computing a scatter of finite number of mock catalogues (see Section 4), using more bins deteriorates the precision at which the elements of the covariance matrices can be estimated. Empirical tests performed on the mock catalogues suggest that the RSD signal is more or less insensitive to the binning choice, while the BAO measurements are optimal at $\sim 8\,h^{-1}\,\text{Mpc}$ (for details see Percival et al. 2013). We bin $r$ in 16 bins of $8\,h^{-1}\,\text{Mpc}$ in size in the range of $24\,h^{-1}< r < 125\,h^{-1}\,\text{Mpc}$ and $\mu$ in 200 bins in $0<\mu<1$, and estimate the correlation function on this two-dimensional grid. The information in the correlation function below $24\,\text{Mpc}\,h^{-1}$ is strongly contaminated by non-linear effects, and the scales above $152\,\text{Mpc}\,h^{-1}$ have low signal-to-noise ratio and contribute little information.

We compress the information in the two-dimensional correlation function by computing the Legendre multipoles with respect to $\mu$.
by approximating the integral with a discrete sum:

$$\hat{\xi}_\ell(r) = \frac{2(\ell + 1)}{2} \int_{-1}^{1} d\mu \hat{\xi}(r, \mu)L_{\ell}(\mu)$$

(7)

$$\approx \frac{2(\ell + 1)}{2} \sum_k \Delta \mu_k \hat{\xi}(r, \mu_k)L_{\ell}(\mu_k),$$

(8)

where $L_{\ell}(\mu)$ is the Legendre polynomial of the order of $\ell$.

In the subsequent analysis, we only use the monopole ($\ell = 0$) and the quadrupole ($\ell = 2$) moments. The higher order moments contain significantly less information and are more difficult to model. (For the contribution of the higher order moments, see e.g. Taruya, Saito & Nishimichi 2011; Kazin, Sanchez & Blanton 2012).

The RSD signal in the measured correlation function varies within the sample due to redshift evolution [via the redshift dependence of $f(z)\sigma_\delta(z)$ and $b(z)\sigma_\delta(z)$]. If we keep track of the redshift of individual galaxy pairs in equation (6), we effectively measure

$$\hat{\xi} = \frac{\sum \xi(z)w_i^2}{\sum w_i^2},$$

(9)

where summation is over individual galaxy pairs contributing to DD counts, $\xi(z)$ is the correlation function at mean redshift of that galaxy pair and $w_i^2$ is the product of the weights of individual galaxies in the $i$th pair. Thus, our measurement is actually a weighted redshift-averaged correlation function. The evolving correlation function can be expanded into Taylor series in redshift around some value of $\bar{z}$:

$$\xi(z) = \xi(\bar{z}) + \frac{d\xi}{dz} \bigg|_{z=\bar{z}} (z - \bar{z}) + O[(z - \bar{z})^2].$$

(10)

Keeping only the first-order term, we find

$$\xi = \xi(\bar{z}) + \frac{d\xi}{dz} \bigg|_{z=\bar{z}} \sum_{i,z} (z - \bar{z})w_i^2,$$

(11)

and the second term disappears if we define

$$\bar{z} = \frac{\sum z_i w_i^2}{\sum w_i^2}.$$  

(12)

If the derivatives of the correlation function of second order and higher are small, the redshift-averaged correlation function is equal to the correlation function at an 'effective' redshift given by equation (12).

The ‘effective’ redshift defined in equation (12) is a function of scale. We adopt $\bar{z} = 0.57$, a value which is close to the $\bar{z}$ computed from the catalogue to better than 1 per cent precision for all scales in the range $24 h^{-1} < r < 152 h^{-1}$ Mpc. We checked that in our fiducial ΛCDM cosmology the contribution from the higher order terms in equation (11) are indeed small for the expected theoretical variations in $f\sigma_8$ within the redshift range. We will therefore interpret our estimates as measurements of the correlation function at this effective redshift.

Fig. 3 shows the measured monopole and quadrupole of the CMASS galaxies along with 1σ error bars (see Section 4 for details of the error estimation). We will use these measurements in our analysis rather than the two-dimensional correlation function presented in Fig. 2.
The multiplicative correction factor is $A = \frac{2}{(n_s - n_b - 1)(n_s - n_b - 4)}$, \quad \text{and} \quad B = \frac{n_s - n_b - 2}{(n_s - n_b - 1)(n_s - n_b - 4)},

where $n_b$ is the length of vector $p$. This accounts for the uncertainties in the determination of the inverse covariance matrix from the finite number of catalogues (for details see Percival et al. 2013). In our case, $n_s = 600$, $n_b = 32$ and $n_p = 5$, which results in $A = 6.25 \times 10^{-6}$ and $B = 1.77 \times 10^{-3}$. The multiplicative correction factor is then 1.04.

In approximating the likelihood by equations (16) and (17), we made two assumptions: that the errors on the monopole and quadrupole are drawn from a multivariate Gaussian distribution (equation 16) and that the dependence of inverse covariance matrix on free parameters is weaker than the dependence of the model $[dIC_{ij}(p)/dp] < \delta_{ij}(p)/dp$ in equation (17).

Non-linear evolution will induce non-Gaussian. To check the validity of the first assumption, we estimate a skewness of $\xi$ in bins of $r$ from the 600 PTHalo mocks using

$S_i(r_i) = \sqrt{600 \sum_i \left( \frac{\xi_i(r_i) - \bar{\xi}(r_i)}{\sigma_i(r_i)} \right)^3 \frac{1}{\sum_i \left( \frac{\xi_i(r_i) - \bar{\xi}(r_i)}{\sigma_i(r_i)} \right)^2} \right]^{1/3}.

(21)

Fig. 5 shows a histogram of the resulting distribution of skewness and the prediction made assuming that the distribution of $\xi_i(r_i)$ is Gaussian. The observed distribution is consistent with the assumption of Gaussianity; therefore, we will ignore the contribution of possible non-Gaussian contributions to the likelihood of $\xi_i(r_i)$.

The validity of our second assumption is helped by the fact that the signal-to-noise ratio is high and the mock catalogues were tuned to reproduce the observed clustering of CMASS sample on average (see Manera et al. 2013 for details).

---

2 We use $n_p = 5$ here even though the total number of fitted parameters is 8, because the three ’shape’ parameters are constrained almost exclusively by the Planck covariance matrix of equation (29) which is not derived from our suite of 600 PTHalo mocks and is assumed to be exact.

---

5 THEORETICAL MODEL

5.1 Modelling multipoles

We use the ‘streaming model’ to compute our theoretical template correlation function. Within the streaming paradigm, the correlation function in redshift space is derived by taking a real space, isotropic correlation function $\xi_i(r_i, r_{\perp})$ and convolving it along the LOS with a probability distribution function of the infall velocity $P$ of a galaxy pair at that separation.

$1 + \xi_i(r_i, s_{\perp}) = \int \left[ 1 + \xi_i'(r_i, s_{\perp}) \right] P(s_{\perp}) \, ds_{\perp},

(22)

where $s_{\parallel}$ and $s_{\perp}$ are the components of a vector in the parallel and perpendicular to the LOS direction; $r_i$ and $r_{\perp}$ are the analogous components in the real space. In the plane-parallel approximation, we adopt here $s_{\parallel} = r_i$. The function $P$ accounts for both quasi-linear infall motions and the random small-scale velocities (’Finger-of-God’ effect; Jackson 1972).

Following Reid & White (2011), we assume

$P(\Delta) = \frac{\exp\left[ -[\Delta - \mu \nu_{\mu}(r, \mu)]^2 / 2\left( \sigma_n^2(r, \mu) + \sigma_F^2 \right) \right]}{\sqrt{2\pi \left( \sigma_n^2(r, \mu) + \sigma_F^2 \right)}},

(23)

and compute the $v_n^2(r, \mu)$ and $\sigma_n^2(r, \mu)$ values using the standard perturbation theory, while the correlation function in the configuration space – $\xi_i'(r)$ – is computed using Lagrangian perturbation...
theory (see Reid & White 2011 for details). The parameter $\sigma_{8,\text{FOG}}^2$ is an isotropic dispersion that accounts for motions of galaxies within their local environment that are approximately uncorrelated with the large-scale velocity field; this parameter is varied within a broad prior consistent with the expected contribution from satellite galaxies; see Reid et al. (2012) for further discussion.

Recently, Wang et al. (2014) extended the results of convolution Lagrangian perturbation (Carlson, Reid & White 2013) and combined them with the ‘streaming model’ to obtain accurate predictions for the two-dimensional correlation function. This improved model is accurate for a wider range of biases than the original model. For the CMASS sample, however, the original implementation of the model in Reid & White (2011) remains accurate enough and is used in this analysis (see also discussion following Fig. 6).

If the real geometry of the Universe differs from the fiducial cosmology used to compute the correlation function, this will result in the additional distortions via the AP effect. To account for this, we rescale the redshift-space correlation function in equation (23) as

$$\xi^\text{obs}(\delta^s_r, \delta^s_\perp) = \xi^\text{fid}(\alpha^s_r, \alpha^s_\perp),$$

where

$$\alpha^s_r = \frac{H^\text{fid}}{H}, \quad \alpha^s_\perp = \frac{D^\text{fid}}{D^\text{fid}},$$

and $H^\text{fid}$ and $D^\text{fid}$ are the Hubble expansion rate and the angular distance in the fiducial cosmology.\(^3\)

The model correlation function depends on the growth rate via $v_\text{ms}$ and $\sigma_{8,\text{FOG}}$. The higher values of $f$ result in higher amplitude of both multipoles. The dependence on the Hubble expansion rate and angular distance arise from the AP effect and are manifested as distortions of the multipole shapes.

Our model has been compared to N-body simulations and shown to fit the anisotropic clustering down to scales of $\sim 25 \ h^{-1} \ Mpc$ with percent level precision (Reid & White 2011; Reid et al. 2012). To check that the PTHalo mocks adequately describe the RSD signature in the range of scales used in the analysis, we fit our model to the mock measurements. For simplicity, we fix the shape of the linear power spectrum to the input value and use the input cosmology to compute radial and angular distances (this is equivalent to fixing $\alpha^s_r = \alpha^s_\perp = 1$) so that the only free parameters are $f$, $b$, and $\sigma_{8,\text{FOG}}$. Fig. 6 shows the distribution of maximum-likelihood (ML) values of $b$ and $f$ recovered from the mock catalogues. The systematic offset between the mean of the ML values for $f$ and the input value of $f$ is of the order of 1 per cent, and the scatter in the ML values (after appropriate rescaling as in Percival et al. 2013) is comparable to the errors produced in Section 6. At least at the two-point level, this shows that the relevant systematic effects in the PTHalo mocks are much less than our measurement precision and can be safely ignored.

Fig. 7 shows the mean values and 1σ error bars recovered by fitting individual PTHalo mocks with the non-linear ‘streaming model’ as a function of minimal scale used in the analysis. The figure also shows the results if we use a linear theory model (Kaiser 1987) with no velocity dispersion nuisance parameter. We find that for the BOSS DR11 data, one would need to fit above $60 \ h^{-1} \ Mpc$ to get unbiased estimates of the growth rate with the linear model. The non-linear model resulted in unbiased fits even when scales down to $25 \ h^{-1} \ Mpc$ were used.

The model predictions for $\xi_{\ell}(r)$ depend on eight parameters. These are parameters determining the shape of the linear correlation function $p_{\text{lin}} = (\Omega_m h^2, \Omega_b h^2, n_s)$, the bias of galaxies $b$, the linear growth rate $f$, two AP parameters $\alpha^s_r$ and $\alpha^s_\perp$, and FOG velocity dispersion $\sigma_{8,\text{FOG}}$. In linear theory, $b$ and $f$ are completely degenerate with $\sigma_8$, and observed clustering is only sensitive to their combination $b\sigma_8$ and $f\sigma_8$. Even though non-linear effects break this degeneracy, it is still present to high degree. To compute non-linear effects on the real-space correlation function as well as mean and variance of infall velocity, we need to specify a value of $\sigma_8(z = 0.57)$. In our analysis, we fix the value of $\sigma_8(z = 0.57) = 0.615$, which is the best-fitting value to Planck data within the ΛCDM-GR model. We checked that model predictions do not change significantly if we keep the values of $b\sigma_8$ and $f\sigma_8$ fixed and vary $\sigma_8$ within ±3σ of the Planck constraints, and therefore, the recovered value of $f\sigma_8$ is not sensitive to the fiducial $\sigma_8$ used to compute non-linear effects. When combining our measurements with Planck data to constrain cosmological models, we do not fix a value of $\sigma_8$ and compute it for each model accordingly (see Section 7).

\(^3\) These parameters were incorrectly defined in the text of Reid et al. (2012), but implemented correctly.
5.2 Modelling DE and gravity

The large-scale properties of the Universe after inflation depend on several variables. First, we have the relative abundances of the main energy-density constituents – radiation $\Omega_\gamma h^2$, baryons $\Omega_b h^2$, dark matter $\Omega_dm h^2$ and DE $\Omega_M h^2$. We must also specify the parameters describing initial conditions at the end of inflation – the spectral index $n_s$, and the amplitude of curvature perturbations $\Delta^2$. Finally, the behaviour of DE can be fully described by its effective equation of state (EoS) $w(z)$ if the perturbations to DE fluid are negligible.

The energy density of radiation is determined with extremely high precision from the temperature of microwave background and is negligible at late times. In addition, the standard inflationary paradigm predicts the Universe to be spatially flat to a high degree, which means that the DE energy density can be expressed in terms of other components $\Omega_{de} = 1 - \Omega_{dm} - \Omega_\gamma$. The parameters $\Omega_{dm}$, $\Omega_\gamma$ and $n_s$ are tightly constrained by CMB data in a way that is independent of late-time behaviour of DE and gravity. The CMB also provides a measurement of the last-scattering surface which depends on DE, but since it utilizes only one integrated measurement of distance, it results in highly degenerate constraints on $w(z)$ and $\Omega_{de}$ if used on its own.

The low-redshift measurements from anisotropic galaxy clustering are strongly complementary to CMB information. The quantities $D_A$ and $H$ depend on $\Omega_m h^2 = \Omega_{dm} h^2 + \Omega_b h^2$ and DE properties, breaking degeneracies of CMB data. The $f$ in the $f\sigma_8$ measurement is sensitive to $\Omega_m$. Relating $\sigma_8$ to $\Delta_8$ in a given model provides a strong additional test of both DE and gravity. The fluctuations in the galaxy field ($\sigma_8$ measured by RSD) are a result of initial fluctuations at recombination ($\Delta^2$ measured by CMB), and their relationship depends on the strength of gravity and expansion of the Universe from $z = 1000$ to the redshift of the galaxy sample. Even small offsets from GR and $\Delta^2$ are amplified and result in large offsets at low redshifts.

Independent probes of distance and expansion rate, such as measurements of luminosity distance from supernovae Type Ia (SNIa) or direct measurements of $H$, further enhance the cosmological constraints.

6 MEASUREMENTS

The measured monopole and quadrupole (see Section 3) along with the covariance matrix estimated from PTHalo mocks (see Section 4) are fitted with the predictions of the streaming model (see Section 5) to derive constraints on the geometry and the growth rate at an effective redshift of $\bar{z} = 0.57$.

The theoretical template for the multipoles depends on the parameters $p = \{b\sigma_8, f\sigma_8, \alpha_\parallel, \alpha_\perp, \Omega_m h^2, \Omega_b h^2, n_s, \sigma_8^2\}$.

Constraints on the shape of the correlation function ($p_{ab}$) from CMB data are significantly tighter than similar constraints obtainable from galaxy clustering only, and these constraints are largely independent of either the behaviour of DE at low redshifts or the nature of gravity (i.e. the values of $\alpha_\parallel, \alpha_\perp$ and $f\sigma_8$ which are of main interest here). To exploit this fact, we multiply the likelihood in equation (16) by a Planck prior on this triplet $L_{\text{full}} = L(p)L_{\text{shape}}(p_{ab})$.

$$\chi^2(p_{ab}) = \Delta p_{ab} I_{C_{ab}} \Delta p_{ab}^T$$

and the mean values of $p_{ab}$ and the $I_{C_{ab}}$ are given by Planck temperature anisotropy data (Planck Collaboration 2013). We use the shape prior derived from the combination of Planck temperature anisotropy data with the WMAP low-multipole polarization likelihood which is (Planck Collaboration 2013)

$$\begin{align*}
\Omega_\gamma h^2 &= 1.186 \times 10^{-1}, \\
\Omega_b h^2 &= 2.218 \times 10^{-2}, \\
n_s &= 9.615 \times 10^{-1},
\end{align*}$$

and covariance matrix

$$\begin{bmatrix}
Dv/r_d & F \\
F & f\sigma_8
\end{bmatrix} = \begin{bmatrix}
2.88 \times 10^{-2} & -9.67 \times 10^{-4} \\
-9.67 \times 10^{-4} & 9.70 \times 10^{-4}
\end{bmatrix}.$$
ratio is independent of cosmology for a wide range of conventional cosmological models (see e.g. Mehta et al. 2012).

Fig. 8 shows the constraints on main cosmological parameters compared to the expectations from the Planck data within standard ΛCDM-GR models along with DR9 results from Reid et al. (2012). The DR11 results are in a good agreement with the Planck predictions; the χ² difference between them is 1.6 for 3 degrees of freedom.

Equations (30) and (31) represent the main results of our work and will be used later to constrain models of DE and MG (see Section 7).

6.1 Comparison to other similar measurements

The companion papers, Anderson et al. (2013), Beutler et al. (2013), Sanchez et al. (2013b) and Chuang et al. (2013), use the same CMASS DR11 data to constrain the distance–redshift relation at z = 0.57.

Fig. 9 shows our measurement of distance along with the result from BAO-only fits and previous similar measurements and Planck predictions for spatially flat ΛCDM model.

In Fig. 9, the label 1D refers to the result derived by fitting the monopole of the correlation function only, while the label 2D refers to the result derived from the fit to the monopole and the quadrupole of the correlation function (see Anderson et al. 2013 for details). Anderson et al. (2013) differ from our analysis in two important aspects. They apply ‘reconstruction’ to the measured galaxy distribution to partially remove the non-linear smearing of the BAO feature, and marginalize over the broad-band shape of the correlation function, so that the estimate of the distance comes from the BAO peak feature alone.

Beutler et al. (2013) and Chuang et al. (2013) measured the distance–redshift relationship using the Legendre moments of power spectrum and correlation function, respectively. Beutler et al. (2013) perform their analysis in Fourier space. The Chuang et al. (2013) analysis is in configuration space but uses a different range of scales and theoretical model than our work. Despite differences in the applied methodology, the estimates are consistent within 1σ error bars.

The growth rate, fσ₈, has also been measured in the same redshift bin by Beutler et al. (2013, DR11), Reid et al. (2012, DR9), Chuang et al. (2013, DR11) and Sanchez et al. (2013b). The comparison of results is presented in Fig. 10. In the Sanchez et al. (2013b) analysis, fσ₈ is a derived parameter computed by combining CMASS data with Planck assuming ΛCDM model; their estimate is perfectly consistent with ours. The Reid et al. (2012) analysis is similar in the range of scales and theoretical modelling to the current paper, but performed on DR9 data set. All measurements are consistent with each other and are somewhat lower than the Planck ΛCDM-GR expectations.
6.1.1 Comparison with our DR9 measurements

The fitting methodology adopted in this paper is identical to that used in our DR9 analysis (Reid et al. 2012), but some of the priors have been updated. We adopt a prior on the linear matter power spectrum shape from Planck rather than WMAP7. Planck has substantially smaller errors, and so we expect the marginalization over the $P(k)$ to contribute negligibly to our error budget in DR11. We also adopted a slightly more conservative top-hat prior on $\sigma^2_{\text{FOG}}$, by increasing the allowed range from 0–40 to 0–50 Mpc$^2$, as the large-scale clustering data alone cannot well constrain this dispersion term; we have checked that this change of prior range does not affect our best-fitting parameter values significantly.

The effective area of DR11 is a factor of 2.5 larger than DR9; in the limit of negligible boundary effects, we would expect the covariance matrix on $D_V/r_s$, $F$ and $f\sigma_8$ to be reduced by the same factor. A direct comparison indicates agreement at the $\sim 15$ per cent level on the diagonals, with DR11 errors slightly larger than expected and with different off-diagonal structure. When projected onto $f\sigma_8$ (at fixed $D_V/r_s$ and $F$), which is the relevant case for the modified gravity constraints we present, our error in DR9 was 0.033 and is 0.028 in DR11, while we would have expected 0.021 from the effective volumes. This situation arises because, as we showed in table 2 of Reid et al. (2012), the prior on $\sigma^2_{\text{FOG}}$ reduces the uncertainty on $f\sigma_8$ in the fixed geometry case substantially. The statistical errors have shrunk significantly in DR11, but we did not assume better prior knowledge on $\sigma^2_{\text{FOG}}$.

A measurement of $\sigma^2_{\text{FOG}}$ from small-scale clustering is in progress (Reid et al., in preparation); if this parameter were perfectly known, the $f\sigma_8$ error would be reduced to 0.017 when the geometric and power spectrum parameters are held fixed.

In DR11, we obtain higher values for $D_V/r_s$ and $f\sigma_8$, which brings us slightly closer to the values predicted by Planck. The $\chi^2$ offset between DR11 and DR9 results is just 0.3 per 3 degrees of freedom.

6.2 Constraints from monopole and quadrupole separately

To determine the separate contribution of monopole and quadrupole, we perform the same fit to each individually. The monopole and quadrupole measurements on their own are unable to break the degeneracy between $b\sigma_8$ and $f\sigma_8$, and can only constrain combinations of the two. Fig. 11 shows the constraints in $b\sigma_8$–$f\sigma_8$ derived from the two multipoles. The solid lines show the expected degeneracy directions based on linear theory predictions.

The quadrupole best constrains $A_2 = (4/3bf + 4/7f^2)\sigma_8^2$, as expected from the linear theory. The amplitude constraints from monopole and quadrupole are collinear to the combination $A_0 = (b^2 + 2/3bf + 1/5f^2)\sigma_8^2$, also as expected from the linear theory. The AP parameters $\alpha_\parallel$ and $\alpha_\perp$ show a qualitatively similar picture. Individual multipoles can only constrain certain combinations of parameters. Fig. 12 presents constraints in the $\alpha_\parallel$–$\alpha_\perp$ plane from the monopole and quadrupole separately. The solid lines show the expected degeneracy directions based on the linear theory predictions.

The principal component of the monopole constraint coincides with $\alpha\parallel = \sqrt{\alpha_\parallel^2 \alpha_\parallel}$ as expected from the linear theory. The principal component of the quadrupole constraint is slightly tilted from the $\alpha_\parallel$ direction; $\alpha\parallel = 1.011 \pm 0.013$ from the monopole and $\alpha\perp = 0.988 \pm 0.091$ from the quadrupole.

6.3 Separate fits to growth and AP

Next we fit the monopole and quadrupole for the growth factor and AP parameters separately. First, we assume that the background expansion follows the predictions of spatially flat $\Lambda$CDM but allows the growth rate to be a free parameter. In this case, the parameters $\alpha_\parallel$ and $\alpha_\perp$ can be computed from $\Omega_m$ and $H_0$. For this model, where the background expansion is assumed to be following the $\Lambda$CDM predictions, we find $f\sigma_8 = 0.447 \pm 0.028$ and $b\sigma_8 = 1.26 \pm 0.02$. The constraint on growth improves to 6 per cent (from 10 per cent) and is perfectly consistent with the result of our more general fit.

Next, we assume that the growth rate follows the predictions of $\Lambda$CDM-GR, but let the expansion rate and the distance–redshift relation vary. In this case, $f\sigma_8$ is computed from $\Omega_m$ but the $\alpha_\parallel$ and $\alpha_\perp$ are free parameters. For this fit, we obtain $\alpha_\parallel = 0.992 \pm 0.023$ and $\alpha_\perp = 1.021 \pm 0.013$. Constraints on $\alpha_\parallel$ move to a lower value and tighten to 2 per cent (from 3 per cent), while constraints on $\alpha_\perp$ move to a higher value and tighten to 1 per cent (from 2 per cent).
the difference between large-scale-only measurements and the ones using all scales above 25 h\(^{-1}\) Mpc is 0.3 for 3 degrees of freedom.

### 7 COSMOLOGICAL IMPLICATIONS

In following subsections, we constrain parameters of standard ΛCDM-GR model by combining our measurements with the CMB and previous, independent BAO measurements. We also examine possible deviations from the standard model by considering phenomenological modifications to both Λ and GR parts.

As a CMB data set, we adopt the recent measurements of CMB temperature fluctuations by the Planck satellite (Planck Collaboration 2013) supplemented by low-\(\ell\) measurements of CMB polarization from the WMAP mission (Bennett et al. 2013) and the high-\(\ell\) measurements from the Atacama Cosmology Telescope (Das et al. 2013) and the South Pole Telescope (Reichart, Shaw & Zahn 2012). For the rest of the paper, we will refer to this combination of CMB data as ePlanck.\(^4\) For our BAO data compilation we use measurements from Beutler et al. (2011, \(z = 0.106\)), Anderson et al. (2013, \(z = 0.32\))\(^5\) and Blake et al. (2011b, \(z = 0.60\)).

To sample cosmological parameter space, we use the Monte Carlo Markov Chain (MCMC) technique implemented by the COSMOMC package (Lewis & Bridle 2002).

#### 7.1 ΛCDM-GR

In a spatially flat ΛCDM-GR model, the expansion history of the Universe and the growth of perturbations can be fully described by six parameters. We choose these to be \(p_{\Lambda CDM} = [\Omega_L, \Omega_b h^2, n_s, \sigma_8(0), \tau, H_0]\). The mean values and 1σ confidence levels are listed in Table 3.

By combining BOSS DR11 results with Planck data, we are able to achieve a 1.6 per cent constraint on \(\Omega_L\), a 1.3 per cent constraint on \(\sigma_8(0)\) and a 1.2 per cent constraint on \(H_0\). After including BAO data set, the constraints improve to 1.0 per cent on \(\Omega_L\) and a 1.0 per cent constraint on \(H_0\), while relative constraint on \(\sigma_8(z = 0)\) does not change. The constraints on \(\Omega_b\) and \(n_s\) are dominated by the information from the ePlanck data set.

\(^4\) When computing the CMB likelihood, we make the same assumptions as Planck Collaboration (2013). For example, we assume a minimum neutrino mass of \(\sum m_\nu = 0.06\) eV. This affects the time of matter-radiation equality and angular-diameter distance to last scattering, as well as early integrated Sachs–Wolfe effect and the lensing potential.

\(^5\) We only use a measurement of BAO from the lower redshift (LOWZ) sample since the measurement from the CMASS sample is highly correlated with our own estimate of \(D_v/r_d\).
7.2 Spatial curvature

We now relax the assumption that the spatial curvature is zero and allow the $\Omega_k$ parameter to vary along with $\Lambda_{\Lambda CDM}$. The posterior confidence regions on curvature and non-relativistic matter density are shown in Fig. 14.

We find $1 + \Omega_k = 0.999 \pm 0.003$ (a 0.3 per cent constraint) when combining BOSS DR11 with ePlanck and $1 + \Omega_k = 1.000 \pm 0.003$ (a 0.3 per cent constraint) when adding the BAO compilation. In both cases, the results are perfectly consistent with a spatially flat Universe.

7.3 Time dependence of dark energy

Alternative models of DE predict a time-dependent EoS $w(z)$. For a wide range of DE models that do not exhibit sudden transitions or large amount of DE at early times, for example models based on cosmological scalar fields, this time-dependence can be adequately parametrized by two parameters

$$w(z) = w_0 + w_a \frac{z}{1 + z}$$

(Chevallier & Polarski 2001; Linder 2003). (For DE models that do not belong to this family see e.g. Wetterich 2004; Doran & Robbers 2006.) This reduces to our standard model for $w_0 = -1$ and $w_a = 0$.

We first set $w_a$ to zero and check if there is an evidence for $w$ to differ from $-1$ on average. The confidence level contours on $w$ and non-relativistic matter density are shown in Fig. 15.

This analysis yields $w = -0.983 \pm 0.075$ (a 8 per cent constraint) when BOSS DR11 is combined with ePlanck data and $w = -0.993 \pm 0.056$ (a 6 per cent constraint) when the BAO compilation is added. In both cases, the results are perfectly consistent with $w= -1$. Our constraints on $w$ differ significantly from the DR9 results presented in Samushia et al. (2013), where we detected up to 2$\sigma$ preference for $w > -1$. This change is mainly due to two differences. We now use ePlanck as our CMB data set, which predicts a higher value for the non-relativistic matter density. Also, our new measurements, although consistent with DR9 results, have moved in the direction that makes them more consistent with the CMB results (see Fig. 8).

Figure 14. Constraints on spatial curvature and non-relativistic matter density from the combination of BOSS DR11 data with CMB and BAO data sets. The contours correspond to 1$\sigma$ and 2$\sigma$ confidence levels in posterior likelihood.

Figure 15. Constraints on $w$ and non-relativistic matter density from the combination of BOSS DR11 data with CMB and BAO data sets. The contours correspond to 1$\sigma$ and 2$\sigma$ confidence levels in posterior likelihood. The $\Lambda CDM$ prediction is consistent at the 1.5$\sigma$ level.

Finally, we consider a model in which the spatial curvature is a free parameter and both $w_0$ and $w_a$ are allowed to vary. The constraints on this model are shown in Fig. 16. The DR11 data alone, even after combining with ePlanck, is not able to break all the degeneracies of this large parameter space. When DR11 and ePlanck are combined with the BAO, we see a preference for larger values of $w_0$ and smaller values of $w_a$. The $\Lambda CDM$ value of $w_0=-1$ and $w_a=0$, however, is still within the 2$\sigma$ confidence level.

7.4 Deviations from GR

MG predict scale dependence of bias and growth rate even in the linear regime and the effect of small-scale screening mechanisms is difficult to model. This makes devising a completely self-consistent test of MG models a non-trivial task. A number of proposals for parametrizing families of MG models have been discussed recently (see e.g. Battye & Pearson 2012; Bloomfield et al. 2012; Baker, Ferreira & Skordis 2013; Mueller, Bean & Watson 2013). These...
parametrizations, however, are difficult to correctly implement in practice for a few reasons. First, they rely on the linear theory and are not expected to work below scales of ~25 h^{-1} Mpc. Secondly, they require a large number of free parameters and such a large parameter space cannot be effectively constrained by current data. For these reasons, we follow the approach of Samushia et al. (2013) and apply several few-parameter consistency tests to our measurements.

We parametrize the growth rate as a function of $\Omega_m$ using

$$f = \left[ \frac{\Omega_m(z)}{E(z)} \right]^\gamma$$

(Linder & Cahn 2008). This approach does not provide a fully self-consistent test of MG models, as MG models predict a more complex change in observables compared to GR. This parametrization is, however, easy to implement and provides a simple consistency test. In GR, we expect the $\gamma$-index to be equal to 0.554. Measuring a significantly higher value would indicate a preference for a force weaker than GR gravity and vice versa. In our fits, we apply a hard prior of $\gamma < 1.0$.

When constraining deviations from GR, we fix DE to be a cosmological constant. We also ignore the CMB power spectrum on large scales ($\ell < 50$) to ensure that CMB data are used only to constrain the background evolution. The parametrizations that we use are not physically motivated and are simply meant to describe effective gravity at low redshifts rather than provide a full model that works accurately at all redshifts up to last-scattering surface.

Constraints on $\gamma$ and $\Omega_m$ are shown in Fig. 17. When combining BOSS DR11 with ePlanck data, we recover $\gamma = 0.691 \pm 0.111$ (a 16 per cent measurement). With the BAO data set, we recover $\gamma = 0.699 \pm 0.110$ (a 16 per cent measurement). The values are within 1.2$\sigma$ confidence of GR values but favour a weaker gravity.

Next, we parametrize the linear equation of growth following the approach of Pogosian et al. (2010) as

$$\ddot{\delta} + (2 + H) \dot{\delta} = \frac{3}{2} \Omega_m(z) G \delta \left( 1 + \mu \alpha^\prime \right),$$

where $\delta$ is a matter overdensity, the overdot denotes a derivative with respect to $\ln a$, $G$ is the gravitational constant, and $\mu$ and $s$ are parameters describing deviations from GR. The GR limit is recovered when $\mu = 0$, where negative values of $\mu$ correspond to weaker than GR gravity and vice versa. The $s$ parameter dictates how rapidly the modifications are set, with larger values of $s$ corresponding to the modifications that appear at later times. Since large values of $s$ correspond to models in which gravity is indistinguishable from GR until some low redshift when the modification suddenly becomes significant, they are basically unconstrained. We place a flat prior of $0 < s < 3$ to avoid this problem. The confidence level contours of $\mu$ and $s$ are shown in Fig. 18.

The GR predictions are within 2$\sigma$ in posterior likelihood. Similar to $\gamma$-parametrization, the data again provide a mild preference for a weaker than GR gravity. This result is consistent with the DR9-based results reported in Samushia et al. (2013).

8 CONCLUSIONS

We have used the anisotropic clustering of galaxies in the BOSS DR11 data set to simultaneously constrain the growth rate, the redshift–distance relationship and the expansion rate at the redshift of $z = 0.57$. Overall, our measurements are in good agreement with the results of the Planck satellite propagated to low redshifts assuming $\Lambda$CDM-GR.

By combining our measurements of $f\sigma_8$, $D_L$ and $f$ with the CMB data we were able to derive tight constraints on basic cosmological parameters and parameters describing deviations from the $\Lambda$CDM-GR model. We were able to constrain the curvature of Universe with 0.3 per cent precision, the DE EoS parameter $w$ with 8 per cent precision and the $\gamma$-index for growth with 16 per cent precision.

When we vary the background expansion within $\Lambda$CDM predictions of the Planck data, we measure the growth rate (parametrized by $\gamma$) to be weaker but consistent within 1.2$\sigma$ of GR predictions. This preference for lower values of growth rate has also been observed in other similar low-redshift measurements (see e.g. Macaulay, Wehus & Eriksen 2013 for discussion). Our measurement of $f\sigma_8$ follows this trend but is closer to the GR predictions compared to the DR9 results of Reid et al. (2012) and the DR11 measurement of Beutler et al. (2013).

Similar measurements from a lower redshift (LOWZ) sample of BOSS galaxies will provide a complementary measurement of the
growth rate in the DE-dominated redshift range of $0.2 < z < 0.43$, which will significantly strengthen the constraining power over possible GR modifications and can potentially increase the significance of the ‘low growth rate’ signal.

APPENDIX A: CMB SHAPE PRIOR

Fig. A1 displays the posterior likelihood of $p_{sh}$ obtainable from DR11 data alone.

The likelihood surface does not close even within $\pm 10\sigma$ of the CMB constraints. Previous studies either fix the shape parameters to their CMB best-fitting values (e.g. Samushia et al. 2012), let $\Omega_m h^2$ vary and fix the rest (e.g. Blake et al. 2011a), or marginalize over them by taking a prior centred around CMB best-fitting values (e.g. Chuang et al. 2012).

We adopt a different approach and apply the CMB shape prior to our galaxy clustering likelihood. Since later we will combine our results with Planck data to obtain constraints on DE and MG parameters, one may be led to an erroneous impression that the CMB data are being double counted. We demonstrate below that this is not the case.

Let $L^C(a, b)$ be a CMB likelihood, where $a$ are shape parameters and $b$ are other parameters that may be related to DE and gravity parameters of interest [$b(w, \gamma, \ldots)$]. Let $L^G(a, c)$ be galaxy likelihood, where $c$ are DE and gravity dependent [$c(w, \gamma, \ldots)$]. For simplicity, assume $a$, $b$ and $c$ to be scalars and that all likelihoods are multivariate Gaussian.

In our approach, we take a CMB shape prior

$$\int L^C(a, b) db$$  \hspace{1cm} (A1)

apply it to galaxy data

$$\int L^C(a, b) L^G(a, c) db da$$  \hspace{1cm} (A2)
and then combine it with full CMB likelihood
\[ L_1(b'(x)c(x)) = \int L^C(a, b) L^G(a, c) L^C(a', b') db da da', \]  
(A3)

where \( x = (w, \gamma, \ldots) \).

Let us compare this expression to that produced by directly combining the two likelihoods
\[ L_2(b(x)c(x)) = \int L^C(a, b) L^G(a, c) da. \]  
(A4)

\( L_1(b, c) \) and \( L_2(b, c) \) are also Gaussian with
\[ \sigma_{1b}^2 = \sigma_{1c}^2 \]  
(A5)

\[ \sigma_{2c}^2 = \frac{\sigma_{2a}^2 + \sigma_{2G}^2 (1 - r_{Gab})}{\sigma_{2a}^2 + \sigma_{2Ga}^2} \sigma_{2Gc}^2 \]  
(A6)

\[ \rho_{1bc} = 0 \]  
(A7)

\[ \sigma_{2b}^2 = \frac{\left( \sigma_{2a}^2 (1 - r_{Cab}) + \sigma_{2Ga}^2 \right) \left( \sigma_{2a}^2 (1 - r_{Cab}) + \sigma_{2Ga}^2 \right)}{\sigma_{2a}^2 (1 - r_{Cab}) + \sigma_{2Ga}^2 (2 - r_{Gab}^2 - \sigma_{2a}^2 + r_{Gab}^2) + \sigma_{2Ga}^2 (1 - r_{Gab})} \sigma_{2Gc}^2 \]  
(A8)

\[ \rho_{2bc} = \frac{\sigma_{2a}^2 (1 - r_{Cab}) + \sigma_{2Ga}^2 (2 - r_{Gab}^2 - \sigma_{2a}^2 + r_{Gab}^2) + \sigma_{2Ga}^2 (1 - r_{Gab})}{\sigma_{2a}^2 (1 - r_{Cab}) + \sigma_{2Ga}^2 (2 - r_{Gab}^2 - \sigma_{2a}^2 + r_{Gab}^2) + \sigma_{2Ga}^2 (1 - r_{Gab})}. \]  
(A9)

\( L_2 \) always encloses \( L_1 \). To first order in \( \sigma_{Ca}/\sigma_{Ga} \)
\[ \sigma_{1b}^2 = \sigma_{1c}^2 \]  
(A10)

\[ \sigma_{2c}^2 = (1 - r_{Gab}) \sigma_{2Gc}^2 \]  
(A11)

\[ \rho_{1bc} = 0 \]  
(A12)

\[ \sigma_{2b}^2 = \sigma_{2c}^2 \]  
(A13)

\[ \rho_{2bc} = \frac{r_{Gab} \sigma_{Ca} \sigma_{Gb} \sigma_{Gc}}{\sigma_{Gb}}. \]  
(A14)

This demonstrates that direct combination of galaxy clustering and CMB data always produces stronger constraints on derived parameters, and therefore the galaxy clustering measurements obtained by assuming a CMB prior on the shape can be combined with the CMB data without double counting the information.
