1 INTRODUCTION

Adaptive optics (AO) is a technique that aims to compensate the phase aberrations induced by atmospheric turbulence. Aberrations are measured by a wave-front sensor (WFS), using observations of a guide star (GS). Corrections are applied by an optical active device, generally a deformable mirror (DM). For the current class of 8–10-m astronomical telescopes, AO typically improves the angular resolution by an order of magnitude, and restores a resolution close to the telescope diffraction limit. Over the past 20 years, AO for astronomy has gone from a demonstration phase to a well-proven and operational technique, and it is now almost universally considered as an essential part of any new large telescope. In addition, to increase the number of targets on which AO can be used, all of the major 8-m telescopes are now equipped with Laser Guide Stars (LGS; see e.g. Wizinowich 2012). AO and LGS-AO observations have enabled major discoveries in astronomy with, among others, the discovery and study of the supermassive black hole at the centre of our Galaxy (e.g. Ghez et al. 2008; Genzel, Eisenhauer & Gillessen 2010), detailed images of the surface of Solar systems bodies (e.g. Hartung et al. 2004; de Pater et al. 2010), or precise morphology and dynamics of very distant galaxies (e.g. Huertas-Company et al. 2008; Cresci et al. 2009; Wright et al. 2009; Carrasco, Conselice & Trujillo 2010).

ABSTRACT

The Gemini multiconjugate adaptive optics system – GeMS, a facility instrument mounted on the Gemini South telescope, delivers a uniform, near diffraction limited images at near-infrared wavelengths (0.95–2.5 µm) over a field of view of 120 arcsec. GeMS is the first sodium layer based multilaser guide star adaptive optics system used in astronomy. It uses five laser guide stars distributed on a 60 arcsec square constellation to measure for atmospheric distortions and two deformable mirrors to compensate for it. In this paper, the second one devoted to describe the GeMS project, we present the commissioning, overall performance and operational scheme of GeMS. Performance of each subsystem is derived from the commissioning results. The typical image quality, expressed in full with at half-maximum, Strehl ratios and variations over the field delivered by the system are then described. A discussion of the main contributor to performance limitation is carried out. Finally, overheads and future system upgrades are described.

Key words: instrumentation: adaptive optics – instrumentation: high angular resolution – telescopes.
The advent of a new generation of AO systems called Wide Field AO (WFAO) mark the beginning of a new era. By using multiple GSs, either LGS or Natural Guide Stars (NGSs), WFAO significantly increases the field of view (FoV) of the AO-corrected images, and the fraction of the sky that can benefit from such correction. Where the first AO systems (also called single-conjugate AO or SCAO) were well suited for observations of bright and relatively compact objects, the new generation of WFAO is opening the path for a multitude of new science studies.

Different flavours of WFAO have been studied over the past years. They all require multiple GSs to perform a tomographic analysis of the atmospheric turbulence. What differentiates the various WFAO systems is how the turbulence correction is applied. Ground Layer AO (GLAO) uses a single DM optically conjugated to the telescope pupil (Rigaut 2001). If the correction is optimized over a FoV larger than the anisoplanatism angle, then only the atmospheric layers close to the ground will be compensated (Ragazzoni et al. 2002), providing a partial, but uniform correction over the field. Another solution, called multi-conjugate AO (MCAO; Dicke 1988; Beckers 1994; Johnston & Welsh 1994) uses several DMs optically conjugated to the main turbulence layers. In that case, all the layers close to the DM altitude conjugation will be compensated, restoring the telescope diffraction limit over FoVs many times larger than the ones achievable with SCAO at near infrared (NIR) wavelengths.

MCAO for night time astronomy was first demonstrated by Multi-conjugated Adaptive optics Demonstrator (MAD), a prototype built at the European Southern Observatory (Marchetti et al. 2003, 2007). MAD used three NGSs, two DMs conjugated at the ground and at an altitude of 8.5 km, and provided a corrected FoV of almost 2 arcmin across. Although MAD successfully demonstrated the gain brought by WFAO over SCAO, it was limited in the number of potential targets due to limiting magnitude of the required NGSs ($\mu m < 12.5$) and, essentially running out of targets, the instrument was decommissioned in 2008. The first multi-LGS WFAO system open for the community was a GLAO system operating at the Multiple Mirror Telescope, which uses three 532 nm Rayleigh LGSs (Baranec et al. 2009). Gemini multi-conjugate adaptive optics system (GeMS), the Gemini MCAO system, is the first sodium based multi-LGS MCAO system.

This paper is the second of a review describing the GeMS project. The first paper (Rigaut et al. 2014 – hereafter Paper I) covers the first part of the history of the project, from the original idea to the first light images. It also includes a detailed description of GeMS, hence only a brief description of the system is given here. GeMS is made by two main subsystems: (i) the Laser Guide Star Facility (LGSF) that includes a 50 W laser and an optical system called Beam Transfer Optics (BTO) that relays the laser light, and controls the LGSs and (ii) the MCAO bench, called Canopus. In short, the 50 W laser is split in 5 × 10 W beams to produce the 5 LGSs projected on the sky at the corners and centre of a 60 arcsec. These LGSs feed five 16 × 16 subapertures Shack–Hartmann WFSs (so-called LGSWFSs). The 2040 slope measurements are used to compute the MCAO high-order correction, correction provided at up to 800 Hz by two DMs conjugated to 0 and 9 km. In addition, up to three visible NGSs provide the measurements for the compensation of the tip–tilt (TT) and anisoplanatic modes. The TT compensation is done by a tip–tilt mirror (TTM) while the tilt-anisoplanatic (TA) modes are compensated by a combination of quadratic modes on DM0 and DM9. A fraction of the light from one of the NGS is directed towards a Slow Focus Sensor (SFS), which controls the LGSWFS zoom to keep the instrument in focus. At the GeMS output, the corrected beam can be steered towards different science instruments attached to the Cassegrain focus instrument cluster. The main instrument used to date is Gemini South Adaptive Optics Imager (GSAOI; McGregor et al. 2004), a 4k × 4k NIR imager covering 85 arcsec × 85 arcsec designed to work at the diffraction limit of the 8-m telescope.

This paper focuses on the commissioning, overall performance and operation scheme of GeMS. The goal of this paper is to give a top-level view of the GeMS capability, that could be used for instance when preparing observations. Section 2 summarizes the commissioning period, and details the performance of the subsystems. Section 3 gives an overview of the System Verification (SV) period, and illustrates the science capability provided by GeMS. Section 4 analyses the top-level performance delivered by GeMS in term of image quality over the field and astrometry precision. Note that this paper does not intend to perform a detailed analysis of the system performance, as this will be presented in a dedicated paper. Section 5 discusses the operational scheme of GeMS, including overheads, and finally Section 6 presents the system upgrades.

2 COMMISSIONING OVERVIEW

2.1 Summary and timeline

In early 2010 October, the decision was made to move Canopus to the telescope and start on-sky commissioning as soon as possible. This decision was motivated by the seasonal weather conditions at Cerro Pachón and the need for clear nights to propagate the laser for efficient commissioning. Canopus’ move from the Gemini La Serena headquarters to the telescope marked the ending of the Assembly Integration and Test phase, and set the beginning of the on-sky commissioning period. Canopus was installed on the telescope on 2010 January 10, and night time commissioning started on 2011 January 20. The first phase of the commissioning lasted five months, with five runs of 4 to 7 nights each. The main focus of this first period was the commissioning of LGSF and checking the Canopus basic functionalities.

After this first commissioning period, in early 2011 June, GeMS entered a planned five-month maintenance period. The Chilean winter yields conditions less favourable for AO observations, and this presented a timely opportunity to fix, repair and upgrade many GeMS systems based on the experience acquired on-sky, as well as to finish tasks that were put on hold prior to the accelerated commissioning plans starting in 2011 January.

A second period of commissioning started in 2011 November, with seven runs of 5 to 9 nights spread over seven months. The objectives of this period were to demonstrate the MCAO correction, conduct GSAOI commissioning and start integrating GeMS into the Gemini science operations. In 2012 June, GeMS entered its second five month shutdown phase. This engineering period was dedicated to implement the required upgrades before GeMS entered into regular operations. The latest phase of commissioning started in 2012 October with three runs of 8 nights each.

In total, 95 nights have been used for the GeMS commissioning. Of these nights, 16 were lost to bad weather and 14 to major technical issues (defined as a problem that completely halts commissioning until it is solved). The number of major technical issues

\footnote{MCAO systems for solar astronomy have been in use since the mid-2000 at the Vacuum Tower Telescope in Tenerife and at the Dunn solar telescope at Sacramento Peak.}
has been decreasing since 2011 December, indicating that the system is getting more stable. Overall, technical issues occurred more frequently at the beginning of the runs, and were generally solved in a very short time frame by the engineering team. However this implies the need for a large engineering team either present on the summit or on-call, complicating the practical organization of the runs. In the next sections we give more details on the commissioning of each subsystem.

2.2 Laser Guide Star Facility commissioning

The LGSF includes the 50 W laser (d’Orgeville et al. 2002; d’Orgeville & McKinnie 2003; Hankla et al. 2006) and the BTO (d’Orgeville et al. 2008) that transports the 50 W beam up the telescope, splits the beam five ways and configures the five 10 W beams for projection by the Laser Launch Telescope (LLT) located behind the Gemini South 8-m telescope secondary mirror. The LGSF was the first subsystem to be commissioned. Most of the LGSF functionalities were tested and commissioned during the 2011 January to March period; however, the final LGSF commissioning continued until 2012. An analysis of the commissioning and performance of the LGSF have been described in d’Orgeville et al. (2012) and Fesquet et al. (2013).

2.2.1 Laser spot size and photon return optimization

Fig. 1 shows an image of the LGS constellation, acquired with the telescope Acquisition Camera (AC), when the telescope has been defocused to be conjugated to 90 km. The spot full width at half-maximum (FWHM) is about 1.3 arcsec and almost Gaussian in shape. The natural seeing (defined at 0.5 μm) was 0.65 arcsec during this acquisition.

LGS short-exposure FWHMs obtained during the 2012 and 2013 laser runs have ranged from 1.2 arcsec (best) to 1.9 arcsec (worst) depending on seeing and actual focus optimization, with a distribution centred near 1.7 arcsec. The original specification for the spot size was to achieve 1 arcsec FWHM on the telescope AC. The LGSWF subaperture FoV is 2.8 arcsec, hence, spot truncation in the edge subapertures may impact the performance when seeing conditions are bad.

The specification was built assuming a laser beam quality of $\mathcal{M}^2 < 1.4$, no optical aberrations induced by the BTO, and a wavefront error (WFE) budget of 95 nm root mean square (rms) for the LLT. The laser beam quality has been measured to be $\mathcal{M}^2 \sim 1.3$, $\mathcal{M}^2 \sim 2.3$, with a strong elongation due to the laser amplifiers geometry (Fesquet et al. 2013). The LLT optical quality has been tested using lucky imaging on natural stars. FWHM of 0.6 arcsec leads to a WFE of $\sim 130$ nm. We also measured that an improvement of up to 0.2 arcsec in the FWHM can be obtained when the beams are centred over the right part of the LLT, revealing issues with the LLT optical quality. Finally, on the other parameters affecting the spot size on-sky, we have measured better performance when the LLT tube covers were open, and when the air supply used in the BTO to ensure over pressure was turned off. These actions reduced the sources of turbulence and internal seeing on the BTO.

The photon return has been monitored over the period of the commissioning, from 2011 to 2013. The main variations observed are due to sodium density fluctuations as described in Neichel et al. (2013). A detailed analysis of the photon return is also presented in d’Orgeville et al. (2012). The most important result is that the return, as measured by the LGSWFs, is a factor of 2 to 5 lower than specifications. The original requirement was giving a range of 250–390 ph/subaperture/frame at the design frame rate of 800 Hz (the subaperture size is $50 \times 50$ cm$^2$), equivalent to 80–120 ph cm$^{-2}$ s$^{-1}$. Sodium return values measured during the 2011–2013 period gives number ranging from 10 to 90 ph cm$^{-2}$ s$^{-1}$. The lower values being observed during the low sodium season (November to February) and the highest one during the high sodium season (May to July). The impact of the low photon return on performance is discussed in Section 4. Several factors can explain the discrepancy between specifications and the actual results. First, the laser spectral format itself is not fulfilling the original requirements: the spectral bandwidth of the laser is twice what was designed originally. This directly and dramatically impacts the interaction with the sodium atoms, as described in e.g. Moussaoui, Holzl, Hackenberg, Holzlöhner et al. (2010) and Rochester et al. (2012). Secondly, the total throughput of the BTO and LLT is 30 per cent below the original specification. The Canopus throughput at 589 nm is also 50 per cent below the original specification. Finally, the control of the polarization of the laser beams has not been implemented yet, which leads to relative differences of 1.5 to 2 in flux between the five beams, varying with telescope elevation. Some of these issues will be addressed in future system upgrades as described in Section 6.

2.2.2 LGSF integration with Canopus

During operation, once the LGSs have been acquired on the Canopus LGSWFs, the TT error measured by each of the WFS is sent to an array of five fast steering mirrors (called FSA for Fast Steering Array) located in the BTO. This forms a closed loop and is running at up to 200 Hz. On top of compensating for possible mechanical flexure, it is also compensating for the uplink TT due to the atmospheric turbulence. It is a critical element of GeMS and the system could not work without this compensation. Closed loop performance of the fast jitter compensation by the FSA platforms...
gives TT residuals of the order of 0.1 arcsec rms and a closed-loop bandwidth of about 5 Hz. TT residuals are twice above the original specification, however, and because the LGS spots are bigger than originally designed, the linearity range of the LGSWFS quadcell is large enough to accommodate these residuals. For a typical spot size of 1 arcsec (measured on a subaperture), the linearity range is \( \pm 0.5 \) arcsec. The FSA mirrors only have a small dynamical range (\( \pm 5 \) arcsec equivalent on-sky), hence their average position is offloaded to a combination of a pointing mirror and a centring mirror, used to adjust both the position of the LGS constellation on-sky and the beams on the LLT. In addition, the rotation computed from the five FSA average positions is offloaded to a ‘K mirror’ (KM) every 10 s to compensate for constellation rotation drifts.

2.3 Canopus commissioning

Canopus commissioning started in 2011 March, and finished in 2011 December, when the first wide-field compensated images were obtained (see Paper I – Section 6).

2.3.1 LGSWFS stepper look-up table

The LGSWFS assembly contains eight stepper mechanisms (two zoom lenses and six magnifiers) used to accommodate for the changes in LGS ranges (changes in telescope elevation or changes in the Na layer altitude), as well as to compensate for flexure and Canopus temperature variations. A look-up table (LUT) is built to ensure that the registration between the five LGSWFS and DM0 is maintained for all accessible LGS ranges, telescope elevation and temperature changes. This LUT is built during day time, using artificial laser sources located at the entrance focal plane of Canopus. Using a model fitting method described in Neichel et al. (2012b), we have checked that the DM9 registration was kept constant when DM0 was properly registered.

A procedure has been developed to measure the misregistration on-sky and check the LUT performance. The method, described in Rigaut et al. (2012), is based on a lock-in detection of a dynamic dithering pattern introduced on DM0. Results measured on-sky show that the LUT maintain the registration below a 10 per cent subaperture error for the full range of elevations and temperatures seen by GeMS.

2.3.2 Centroid gains

As discussed in Paper I (section 4.6), centroid gains calibration have been of particular concern. This was especially critical due to the large amount of Non-Common Path Aberrations (NCPA; see Section 2.3.6) as an error on the centroid gain will translate directly into a NCPA compensation error (Véran & Herriot 2000).

When using the Canopus LGS calibration sources, because there is no turbulence, we were able to use a simple method that consists in swiping the LGS spots in front of the LGS WFS (thus through the quadcell in each subaperture) using the TTM. Assuming the latter is well calibrated, one obtains this way the quadcell transfer function, from which the centroid gains can be readily fitted.

On the sky however, the constraints are different. There is a large amount of natural disturbance (turbulence), and several methods have been proposed in the literature (Véran & Herriot 2000; van Dam 2005; Gratadour & Rigaut 2007) to calibrate the centroid gains online. The method that has been selected for GeMS is based on dithering. A small disturbance is introduced at a given frequency, the amount of this disturbance, as detected by the WFS, is retrieved by lock-in detection. The ratio between what is introduced and what is detected is an estimator of the error on the centroid gains.

The original plan for GeMS was to use individual rotations of each of the LGS (uplink) as a disturbance using the BTO FSA (Paper I, section 4.4.4). This has the important advantage to have no direct impact on the image quality on the science path, thus one can possibly use fairly large dithering amplitudes, increasing the measurements signal-to-noise ratio (SNR). Unfortunately, this was hampered by cross-calibration errors between the FSA mirrors, and more importantly, by distortion of the dithering signal due to the FSA mirrors hitting their end-of-travel limits.

A second attempt was made by introducing a similar rotating motion, but introduced by the TTM. This solved the issues encountered with the FSA method but it impacted the science image significantly. It was found that 10 milliarcsec (radius of circular motion) was the minimum quantity to get a measurement relatively immune from noise. The method was also heavily affected by narrow vibration peaks, which eventually disqualified it.

The third disturbance type that was experimented with and eventually adopted is to induce a checkerboard-like mode using the DM (Rigaut et al. 2011). This makes the LGS spots rotate in opposite direction in ‘even’ and ‘odd’ subapertures. In addition, and prior to the temporal filtering provided by the lock-in detection, a spatial projection onto this checkerboard mode is performed, providing additional filtering of noise and other natural contributors; in particular, it provides total immunity to vibration. A checkerboard mode amplitude of 30 nm rms is used which, at the current level of performance, does not induce any detectable effects on the images [the effect of the checkerboard mode will be to create satellites around the point spread function (PSF) cores]. This method was cross-checked with the results obtained by dithering the TTM described above and the results are consistent within less than 2 per cent.

2.3.3 High-order loop and related offloads

The first LGS closed loop was achieved as soon as 2011 March, however, it took several more runs to be able to optimize the high-order loop and provide high-order corrections over the field. One of the issue was related to centroid gain as discussed in the previous section. Another main issue that was encountered was related to the Rayleigh contamination (or fratricide effect), as described in Neichel et al. (2011). It was found that due to fast laser power variations, and spatial jitter of the beams on the LLT due to the optical location of the FSA, it was not possible to calibrate accurately enough the Rayleigh background in order to subtract it (see Paper I – section 5.3.2). This leads to large LGSWFS slope errors and means that the Rayleigh-affected subapertures (about 20 per cent of all subapertures) have to be discarded.

The tomographic phase reconstruction is done by the reconstructor matrix \( R \). \( R \) is a regularized least-squares inversion of the interaction matrix, \( M \) and is given by

\[
R = (1 - F_0)(M^TW^{-1}M + \alpha C_\theta^{-1} + \beta F_0)^{-1}M^TW^{-1}(1 - F_0).
\]

The terms in equation (1) are as follows:

(i) \( F_0 \) are the filtered modes in actuator space. For MCAO, they consist of piston, tip and tilt on the ground-layer DM, and the same modes plus focus and astigmatism for the high-altitude DM(s),

(ii) \( W \) is a weighting matrix that weights the centroid measurements from partially illuminated subapertures less heavily than fully
illuminated ones, and also weighs smaller spots more heavily than larger ones.

(iii) $\alpha$ is a regularization parameter that can be configured depending on the SNR.

(iv) $C_s$ is the covariance matrix of the actuator commands based on open-loop turbulence statistics.

(v) $\beta$ is a constant adjusted to remove the filtered modes in the least-squares inversion, and

(vi) $F_t$ are the filtered centroids to remove average TT in each WFS.

The interaction matrix relates the voltages on the DM actuators to the measured centroids on the WFSs. Conceptually, they are calculated by poking one actuator at a time and measuring the change in the centroids. A much faster way to measure the interaction matrix is to poke each actuator with a separate temporal frequency, take a Circular Buffer of the centroids and the actuator commands, and perform a least-squares fit of the centroids to the commands. This technique results in a fast measurement of the interaction matrix (about two minutes) and is similar to techniques used to measure the interaction matrix on-sky with system using an adaptive secondary mirror (Esposito et al. 2006). The interaction matrix is a function of GS altitude and is calculated every 10 km from 90 to 140 km. For this, the interaction matrix is measured using the internal calibration sources.

The performance of the high-order loop depends on a number of parameters, but can be characterized by the residual rms of the slopes seen by the five LGSWFSs. The residual slopes rms include errors related to the bandwidth error (also called servo lag), the tomography error and the noise of the five LGSWFSs. Part of the noise measured on the residual slopes is filtered by the loop, and hence should be extracted from the rms. We estimate the noise by taking the high-frequency part of the power spectra. Typical WFE corresponding to these LGSWFS noise corrected residual slope rms are of the order of 350 nm, with a range spanning 200 to 600 nm. The original specification of the error budget was allowing less than 200 nm for the high-order terms (Ellerbroek et al. 2003). The main factor affecting the performance are discussed in Section 4.4.

2.3.4 NGS loop and related offloads

The TT signal coming from the three probes (six measurements) is used to compute the weighted average TT (two modes compensated by the TTM), the TA modes (three modes compensated by driving quadratic modes on the high-altitude DM) and a global rotation mode (used to adjust the tracking of the Cassegrain Rotator). Thus, there are three parts to the reconstructor.

A minimum-variance reconstructor was implemented for the TT and tilt-anisoplanatism modes based on van Dam et al. (2013). First, a series of points is defined where we would like to optimize the TT correction (the ‘science targets’). Here, we use nine targets in a regular square grid between $-30$ arcsec and $+30$ arcsec. Then we estimate the TT, $\tilde{s}_t$ at each point in the science field based on the TT measurements, $s_{mn}$ using

$$\tilde{s}_t = C_{rm}(C_{mn} + C_{nr})^{-1}s_{nr}, \quad (2)$$

where $C_{mn}$ is the covariance matrix between the TT in the science target and the WFS directions, $C_{nm}$ is the covariance matrix for the TT in the WFS directions and $C_{nr}$ is the covariance matrix for the measurement noise. Finally, we perform a least-squares fit to find the TT, tilt-anisoplanatism and Cassegrain rotator commands that minimize the residual errors at the science target locations.

The performance of the TT and TA loop depends on the asterism geometry and NGSs magnitude. NGS limiting magnitude is discussed in Section 4.4. At first order, the best constellations are the ones with three bright NGSs that span the largest area of the FoV. An estimation of the TT and TA loop performance is given by the rms of the residual NGS slopes. A typical value for this rms error is of the order of 15 milliarcsec, ranging from 10 to 40 milliarcsec. Original specification was giving less than 10 milliarcsec for this error term when working with bright NGS (Rigaut 2000). This residual includes the bandwidth and the noise error, and, as in the LGS case, are compensated for the high-frequency part of the noise. Vibrations can also affect this residual error term. A very low level of vibrations has been measured using the Canopus calibration sources, with a jitter of 6 milliarcsec rms for tip and tilt, mainly due to peak at 55 Hz induced by the cry-coolers of GSAOI (Rodriguez et al. 2011). On-sky, more vibrations are often seen on the power spectra of the residual slopes (Guesalaga et al. 2012). Low-frequency vibrations ($<20$ Hz) are believed to be due to the secondary mirror of the telescope. A large vibration peak around 85 Hz is also intermittently detected, accounting for ~20 milliarcsec, the origin of this peak is unknown. The use of advanced controllers to optimally filter these vibrations is under study for GeMS (Guesalaga et al. 2012, 2013). The performance of the TA loop is not affected by vibrations, however, the presence of large optical distortions in the NGSWFS focal plane prevents to close this loop during observations that would require telescope dithers larger than 10 arcsec (see Paper I – section 5.3.5).

2.3.5 Slow focus sensor loop

Because the LGSs are used to compensate for atmospheric focus, any changes in the sodium layer altitude cannot be disentangled from real atmospheric focus changes and will induce a focus drift. To prevent this from happening, the SFS continuously measures defocus on one of the NGSWFS. The SFS is a $2 \times 2$ Shack-Hartmann WFS. The focus error measured by the SFS is used to adjust the position of the LGWSWF zoom, forming a feedback loop that compensates the focus error on the SFS, and consequently in the science focal plane (the focus flexure between the Canopus SFS and the science instrument is essentially zero).

The SFS loop update rate is ranging from 1 s to 5 min, depending on the GS magnitude. We have estimated that 50 nm of focus [this corresponds to a loss of 4 per cent of Strehl ratio (SR) in $H$ band] corresponds to a centroiding accuracy in the SFS of 0.1 pixels. Such accuracy can be obtained with a 1 s exposure time for an NGS with $m_R < 13.0$. As a result, the current limiting magnitude for the SFS is $m_R = 16.7$. Hence, whenever possible, the brightest of the NGS is used on the guide probe that contains the SFS, providing enough light to allow the TT/SFS split.

2.3.6 Non-common path aberrations

The principle of NCNA compensation in GeMS has been described in detail in Paper I, section 4.5.2. Fig. 2 shows the evolution of the field-averaged static $H$-band SR along the iterative NCNA optimization process. This typically uses 16 diffraction limited calibration sources spread over the GSAOI detectors. Initial SR values vary between about 15 and 70 per cent. The figure shows that the process converges in 3 to 4 iterations, and reaches an average SR of $88 \pm 0.7$ per cent. Note that the last point shows a slightly lower average SR than the previous iteration. However, it has a three times lower rms,
which probably explains the lower average Strehl as an important weight was given to uniformity in the minimization criteria. The original specification was targeting for and averaged SR of 90 per cent. Tests were performed when optimizing the performance in only one direction. In that case, a maximal SR of 96 per cent can be reached. An important question is of course why the optimization stops short of the single direction performance. There are several reasons for that as given below.

(i) **Non-correctable aberrations.** Aberrations that are induced by optics not conjugated to one of the DM can only be partially compensated (remember the compensation has to be done over the whole FoV, not only on-axis). Only aberrations up to astigmatism are fully correctable by the DMs if they occur on optics not within the 0–9 km altitude conjugation. That includes optics in the science path, but, given the procedure followed, also the optics in the WFS path (to avoid being affected by the large aberrations between the LGS WFS arms, the slope offsets at rest are absorbed in the initial slope offsets).

(ii) **Model calibration errors.** Any difference between the numerical model and the actual system. Misregistration error is probably the major one, but there are others.

(iii) **Modelling limitations.** Any effects that are not included in the numerical model and can lead to bias estimations. For example, single wavelength image formation, non-linearities in the WFS, etc.

(iv) **Noise.** Science imaging detector noise, noise induced by bench local turbulence, etc.

In the final adopted procedure, the focus is induced using DM0. This is effected using slope offsets, thus is not impacted by linearity properties of the DM. However, it will be impacted by linearity of the LGS WFS, which is another potential source of error. One image on each side of focus is generally taken, with no in-focus image (mostly for dynamical range considerations). One iteration, including two GSAOI images plus all the overhead of closing the loop, etc. takes typically 6 min.

**2.4 GSAOI commissioning**

All of the GeMS commissioning has been done using GSAOI. The GeMS review – II. MNRAS 440, 1002–1019 (2014)

GSAOI is the NIR imager dedicated to GeMS (McGregor et al. 2004). It was built at the Australian National University (ANU). It uses four Hawaii-2RG 2k × 2k arrays, forming a 4k × 4k detector covering approximately 85 arcsec × 85 arcsec at 0.02 arcsec per pixel. It comes with a suite of broad and narrow band filters, and has excellent image quality (H-band Strehl in excess of 97 per cent). It is capable of Fowler sampling, and offers On-Detector Guide Window (ODGW) capabilities (up to four, i.e. one per detector, see Young et al. 2012) to supplement or replace the Canopus NGS TT WFS when bright enough NIR GSs are available (see Section 6). ODGW can also be used to guide on a faint star for flexure compensation (the signal is fed to the NGS TT WFS as an offset).

The commissioning of GSAOI per se was performed in parallel to the GeMS commissioning. A comprehensive summary of the GSAOI performance, including the characterization of the linearity, gain and noise of the detectors, as well as the photometric zero-points, system throughput, limiting magnitude and sky brightness can be found in Carrasco et al. (2012). For point source observations, Carrasco et al. (2012) show that a SNR of 10 could be obtained in 1 h integration for K=23 magnitude stars.

**3 SYSTEM VERIFICATION AND SHARED RISK PERIOD OVERVIEW**

The SV period started in 2012 December, one year after GeMS’ first light, and lasted three months. The SV programmes provide an end-to-end test of a new instrument or capability, from the proposal process to data delivery, prior to offering it to the community for general use. With GeMS/GSAOI, one main objective was to demonstrate the gain brought by MCAO on a large variety of science topics, including extended sources, crowded fields and faint targets. 23 programmes were submitted, requesting a total of 138 h. Of these, 13 were selected for execution between 2012 December and 2013 March, for a total of 60 h. 12 targets out of the 13 selected were observed during the course of 18 nights. The system efficiency shows that about 20 per cent of extra time was required to complete the programmes, and that approximately 20 per cent of the observing time was lost due to fault.

SV was immediately followed by a first semester of operations, offered in shared-risk mode, from 2013 March to June. Around 80 h were offered, for 11 programmes, out of which 8 were completed, and 2 started (completion rate of 85 per cent in terms of observing hours). The system efficiency improved during this period, with only about 5 per cent of extra time to complete the programmes, and about 10 per cent lost due to fault.

Fig. 3 shows R136, one of the target observed during the SV period. R136 is a compact star cluster located in 30 Doradus, in the Large Magellanic Cloud. Star clusters are one of the main science cases for GeMS. Crowded fields are where AO/MCAO brings its largest gains. By ‘compacting’ the PSF it brings out the faintest stars in the cluster which are crucial to study star formation in these environments. In addition, by delivering a uniform performance over fields that encompass most globular star cluster sizes, MCAO greatly improves the photometric precision on these crowded fields, and opens the way for a better understanding of the clusters stellar population, particularly of its age, any evidence for multiple stellar populations and the distribution of low-mass stars. The NGC1851 globular cluster image, presented in Fig. 4 and also observed during the GeMS/GSAOI SV period, is another good illustration of the gain brought by GeMS for the star cluster science case. These data were acquired with only one NGS, located close to the centre of the field, to allow for large telescope dithers (see Section 5.3.1). The

average FWHM in the whole image is 95 arcsec. The effect of the TT anisokinetism can be seen on the edge of the field, however the rms variations of the FWHM is only 12 per cent in this 100 arcsec × 100 arcsec image.

Fig. 5 shows another example of a target observed during the SV period; Abell 780 (better known as Hydra A) is a rich cluster of galaxies 840 million light-years distant. For this target, only two NGS have been used, one of them located at the bottom left of the image shown in Fig. 5, the other one located out of the field, on the top left. Even with only two NGSs, the performance is highly uniform over the field, with an average FWHM of 0.077 arcsec. Such performance, at such distance from any usable NGS by a SCAO-LGS system, is unique to GeMS. Indeed, in a SCAO system, even when using a LGS, the target of interest must lie close enough to the NGS used for TT measurements. GeMS is using three NGSs, which can appear to be more restrictive than the SCAO-LGS mode, however, these NGSs can be anywhere in a 120 arcsec diameter acquisition FoV. Hence, the science target can be as distant as 60 arcsec from the NGS, and because of the MCAO correction, the performance will be essentially as good as if the target would have been closer to the NGS. This is particularly interesting in extragalactic studies, which usually suffer from a low NGS and target density.

4 OVERALL PERFORMANCE

This section summarizes the overall performance delivered by the instrument. There are many parameters that are affecting the performance, including among others, natural seeing, NGS constellation, the number of NGSs and their brightnesses, LGS photon return (this parameter varies seasonally), turbulence speed ($\tau_0$) and profile ($C_N^2$), non-common path aberrations and other AO optimization and calibration parameters. It is out of the scope of this paper to present an in-depth analysis of the performance delivered by GeMS. Instead, we focus on the averaged performance, and we identify the main contributors limiting the final results. A detailed performance analysis will be presented in a dedicated paper.

One important point regarding the performance analysis is that, for space restriction reasons in the AO bench, there are no turbulence simulators in GeMS. Hence, no formal performance characterization has been carried out when the instrument was in the laboratory and all of the performance characterization had to be done with
4.1 Delivered image quality

The delivered SRs and FWHMs measured under different natural seeing conditions are shown in Fig. 6. The results are based on images observed with a constellation of three NGSs and with exposure times between 10 and 180 s. They are, respectively, 950 points for the K-band images (red dots), 454 points for the H-band images (green dots) and 243 points for the J-band images (blue dots). The median natural seeing over these observations is 0.73 arcsec (defined at 0.5 μm). For reference, the diffraction limited FWHM are, respectively, 0.031, 0.043 and 0.055 arcsec for J, H and K-band filters.

Another way to present the performance is to look at the delivered image quality for a given fraction of the observing time. This is what is presented in Table 1. Note that by observing time, we intend the time when GeMS is observing, and not the overall telescope observing time. For instance, we see that 50 per cent of the time, GeMS delivers a FWHM of 0.075 arcsec (or better) in H band. In Section 4.4, we discuss in more detail the limitations of the current system performance.

In terms of performance uniformity over the field, MCAO brings very large gains over classical AO. Based on the data acquired during the SV, and only focusing on targets with 3 NGS, we derived an average variation of the FWHM across the images of the order of 4 per cent relative rms over a field of one square arcmin. The peak to peak variations are of the order of 12 per cent of the average FWHM.

Fig. 7 shows one example of the Strehl and FWHM distribution for the Galactic globular cluster NGC288, observed during the commissioning period (See fig. 5 in Paper I). We chose this target as performance is fairly typical. The NGS constellation used is shown with the black triangle, observations were done in the H-band filter. The average FWHM is 0.08 arcsec, the corresponding average SR
is 17 per cent. The FWHM rms variation over the central square arcmin is 2 milliarcsec (11 milliarcsec peak to peak). Fig. 7 is just one example, and a detailed analysis of the performance uniformity, and in particular its variations with the NGS constellations, will be presented in a forthcoming paper. The theoretical impact of the NGS constellation on performance variations over the field can be estimated via an algorithm presented in Section 5.6.

4.2 The MCAO PSF

The MCAO PSF has a different shape than for regular SCAO. The main difference comes from generalized fitting (Rigaut, Ellerbroek & Flicker 2000). Generalized fitting – sometimes called generalized aliasing – results from the fact that the phase corrector is not continuous in altitude, but instead made of a finite number of DMs, conjugated to discrete altitudes. Because the correction is effected over a finite FoV, it is impossible for the system to correct the perturbations at the DM cut-off frequency over the whole column of turbulence (Ragazzoni et al. 2002). As the distance of a layer to the nearest DM increases, the fitting error increases, hence the term generalized fitting. The residual phase error is thus a superposition of residual phases that have a different fitting error depending on the altitude at which they originated. This results in PSFs with Lorentzian profiles, with a narrow central core but without well-defined airy rings nor the well-defined dual core-halo shape usual to classical AO correction. The best functional form fitting the GeMS PSFs is

$$f(r) = g^2 / (g^2 + |r|^2).$$

(3)

Fig. 8 shows an example of a typical PSF profile.

4.3 Astrometry performance

MCAO, having the ability to compensate for plate scale and dynamic atmospheric-induced field distortions, could potentially allow us to reach better astrometric performance than previous AO systems. This section gives a top-level view of the astrometric performance delivered by GeMS, when using 3 bright NGS, and under typical system performance. A full analysis of the astrometric performance, including the impact of the NGS brightness and geometry, is pending.
Figure 6. SR (top) and FWHM (bottom) distribution versus natural seeing. $K$-band data are represented by the red circles, $H$ band by the green squares and $J$ band by the blue triangles. Full lines are median values of SR and FWHM for 0.1 arcsec seeing bins.

Figure 7. FWHM (top) and SR (bottom) maps for the NGC288 target.

The first astrometric performance estimation delivered by GeMS has been carried out in Rigaut et al. (2012). This study shows that, on a single epoch, a relative astrometric precision of 0.4 milliarcsec could be achieved for a 3 min total exposure in $H$ band. In addition, Rigaut et al. (2012) demonstrated that the errors were coming from random sources, uncorrelated from image to image, and that no systematic error could have been detected over the course of 45 min. These single epoch results were confirmed by deeper observations carried-out by Ammons et al. (2013) and Lu et al. (2013). Lu et al. (2013), using observations on NGC1851, demonstrated that an astrometric accuracy of 0.2 milliarcsec could be reached for stars with $K < 12$ and for a total exposure time of 600 s, made by 20 exposures of 30 s each. However, using a data set obtained over the course of 6 months, they found a systematic error of about 1 milliarcsec.
for multi-epoch observations. They also evidenced that due to large optical distortions in the images, best astrometric results are obtained only for non-dithered observations.

The source of the astrometric drift for multi-epoch observations has not been identified clearly yet. The AO bench of GeMS is using a simple two Off-Axis Parabolas optical relay. This relay provides a clean pupil re-imaging, with little pupil distortion, but introduces a significant amount of distortions in the output focal plane. A comparison of the GeMS+GSAOI images with Hubble Space Telescope images shows a distortion pattern of up to a couple of arcseconds (Rigaut et al. 2012). Most of the distortion pattern is static, and can be calibrated out. However, it is possible that the distortion field is evolving from one epoch to the next, impacting the ultimate astrometric performance. It might be due to changes in the gravity vector (the AO bench is mounted on the Gemini Cassegrain focus) or in the environmental parameters (temperature, humidity). As the amount of static distortion is large, even a small drift will have an impact on the final astrometric performance. In crowded fields like the Galactic Center and star clusters, the large number of stars could be enough to fit high-order polynomials to remove changing distortion. For sparse-field applications, such as using high-precision astrometry of bright stars to measure masses of orbiting exoplanets, the number of stars in the field is generally not enough to use such a method.

### 4.4 Performance limitations

The current GeMS performance is below the level specified in the original functional Performance Requirement Document (PDR; e.g. Rigaut & Roy 2001). Table 2 summarizes the error budget described in Section 2.3, and compares the actual performance of the system, with the original figures from the PDR. From the PDR, the predicted SR for an observation at 30° elevation, and for a median $r_0$ of 0.166 m defined at 0.55 μm, is 31 per cent in $H$ band. This translates into a global error budget of 285 nm rms. The median zenith angle measured from the actual data is 27°, hence close to the PDR one. Then, according to Fig. 6, for similar seeing conditions as the PDR, the observed median $H$-band SR is 12 per cent (maximum of 20 per cent), which translates into a global error budget of 380 nm rms (respectively, 330 nm rms). The original PDR document is distributing the error budget between three main contributors: telescope limitations, instrumental limitations and MCAO system. Each of this contributor being divided into subcontributors. From the on-sky performance analysis, we do not have a way to disentangle the contributors of the measured error budget in order to get the same detailed analysis as in the PDR. Therefore, we have tried to combine some of the PDR contributors to match the observed error terms. We do not aim to produce a precise error budget, but rather to draw the main tendencies, and highlight the main discrepancies. The next two sections (Sections 4.4.1 and 4.4.2) are giving more details on the distribution of the high-order error terms. Note that the PDR error estimation is concatenating the contribution of the low-order (NGS) and high-order (LGS) terms, but assumes a case of three bright NGS. For bright NGS, the error due to TT and tilt-anisoplanatism induces a SR reduction by a factor of 0.877 (Rigaut 2000), which translates into 95 nm rms of residual aberrations. This includes residual telescope wind shake. The residual TT jitter measured with GeMS is 15 milliarcsec rms, which translates into 140 nm rms of residual aberrations. The NCPA term estimated at PDR includes the ‘instrument limitations’ and was evaluated to be 65 nm rms. From the results of Section 2.3.6, we evaluate the measured NCPA term to be 90 nm rms. Finally, the remaining terms of the PDR error budget are allocated to the high-order loop. This corresponds to 260 nm rms, while results from Section 2.3.3, gives a typical 350 nm rms measured on-sky. All these results are summarized in Table 2.

According to Table 2, the main discrepancy between PDR and actual performance resides in the high-order terms (see Section 2.3.3). The high-order performance limitations can be split between noise, servo lag and tomography. The first two terms (noise and servo lag) are intrinsically linked as with GeMS, the number of photons per subaperture and per frame is usually kept constant by adjusting the high-order loop frame rate. Following the method described in Rigaut et al. (2012), we analyse the high-order residual slopes in order to disentangle the contribution of the different error terms.

4.4.1 Noise and servo lag error

The system is generally operated at about 140 to 160 ph/subaperture/frame equivalent to between 35 and 40 ph/pixel/frame, as the LGSWFs have 2 × 2 pixels/subaperture. The LGSWF sampling frequency is adjusted to maintain this flux level. The noise error estimated from the telemetry data is of the order of 80 nm rms, ranging from 40 to 120 nm. During the low sodium season (Austral summer) a typical guide rate is about 200 Hz, while during medium to high sodium season (Austral autumn to spring) the guide rate varies between 400 and 800 Hz. GeMS has been design to work at a nominal frame rate of 800 Hz, hence the servo lag error is often large, especially during the Austral summer. We estimated that the servo lag error was of the order of 200 nm rms, ranging from 100 to 300 nm. Fig. 9 illustrates the impact of the laser photon return on the performance. As mentioned in Section 4, there are many parameters affecting the performance (e.g. natural seeing), which explain the large dispersion. However, and despite this dispersion, a clear tendency can be drawn, demonstrating the impact of the low photon return.

Over the period from 2012 December to 2013 June, the laser performance has been stable and the laser has delivered an average power of 42 W (Fesquet et al. 2013). This however is short of the original 50 W specification, and is worsened by the lower-than-specified throughput of the BTO, LLT and Canopus, and the lower-than-specified coupling efficiency of the GeMS laser with the sodium atoms due to its spectral format (Neichel et al. 2013). Plans for upgrades are discussed in Section 6.3.

4.4.2 Generalized fitting (tomographic error)

Disentangling the impact of the tomographic error is more complex as it strongly depends on the CN2 profile. Vidal et al. (2013) illustrate a case where, for a same target, same photon return and same natural seeing, the performance drops by a factor of 2 from one night to the next, only due to the CN2 distribution. Following the method described in Rigaut et al. (2012), we identified the tomographic error term based on the fact that the tomographic/generalized fitting error is filtered by the reconstructor and thus is not affected by the close loop transfer functions. Hence, its high-frequency part (essentially, the noise) will be flat. For the data analysed in this paper, we measure an averaged tomographic error of 280 nm rms, ranging from 150 to 450 nm. Part of the tomographic error can be explained by the fact that, following technical problems with one of the DMs (see Paper I, section 5.3.3), Canopus currently uses only two DMs (at 0 and 9 km with 0.5 and 1 m pitch, respectively) instead of the three initially planned (0, 4.5 and 9 km with 0.5, 0.5 and 1 m pitch, respectively). This reduces the number of active actuators from 684 (design) down to 360 (current). Even though the performance will not simply scale with the number of actuators (the missing ones were aimed to deal with mid-turbulence layers where there is less turbulence than on the ground for instance), it can be easily conceived that this will reduce performance in most of the cases, and will certainly make the system performance less robust to changes in the CN2 profile. From simulations, we have estimated the impact on performance to be of the order of an H-band SR loss of 5 per cent for typical CN2 profiles, but can be significantly more for unfavourable CN2 profiles. In effect, the current two-DM system can be viewed as a fairly potent GLAO system (17 × 17 actuators across M1) with an additional low-order DM at altitude (9 × 9 actuator across M1).
4.4.3 Other limiting factors

As stated above, the main performance limitations are related to the high-order loop. On top of this, there are a number of items that are affecting performance that we try to summarize in this section. Note that this list is not exhaustive, but includes the factors that degrade the performance the most. It is also interesting to note that these limiting factors were not foreseen during the PDR phase. Computing the quantitative impact of each of these terms is not trivial, and we mostly focus on qualitative estimation here.

(i) FSA limited dynamical range. When seeing is strong (e.g. >1 arcsec) and/or if the static optical alignment of the LGS constellation is not perfectly optimized, the FSA are often hitting their rails. This is currently the main cause of loops instabilities. This also means that the LGS spots are not properly centred, and the quadcells may be working in the non-linear regime. This effect is particularly impacting the performance as the WFS pixels are relatively small (1.38 arcsec) and the five LGS spots are not perfectly aligned with the WFS field spots. Hence vignetting with the field stop may be an issue. This latter alignment issue is intrinsic of the LGSWFS design, and could not be improved. The static constellation alignment has been improved of the years, however, due to mechanical limitations and difficult access (the optics are located behind the secondary mirror of the telescope) the best accuracy that was reached is \(\sim 1.5\) arcsec (equivalent on-sky) when the total dynamical range is 5 arcsec. It is difficult to quantify the impact on performance of such an effect and generally, only one out of the five LGS will go in the non-linear regime. This usually has a dramatic impact on the tomographic reconstruction, as differential aberrations between the LGSWFS will drive DM9 to the wrong shape. When this happens, strong differential elongations are seen across the science field, with amplitudes of 0.1 arcsec or more.

(ii) DM saturation. The original dynamical range of the DMs was \(\pm 4\) \(\mu\)m. However, and due to the issues encountered with DM0, the driving voltages have been reduced by 10 per cent in order to try to preserve the DM lifetime. This reduced the DM stroke proportionally. Moreover, protections have been implemented in order to avoid strong and recurrent DM saturation on-sky: the high-order loop is automatically opened if more than 10 per cent of the actuators are saturated on each DM, for more than 10 frames. In operations, and to avoid DM saturations, this implies to work with a lower loop gains and a higher loop leak than is optimal, thereby increasing the servo lag error. An approximate estimation of the impact of this error, based on the error transfer function of the system, gives around 40 nm rms.

(iii) Quasi-static aberrations. A large fraction of the NCPA error budget is due to aberrations introduced at the LGSWFS level. Differential aberrations at the LGSWFS level would produce a non-tomographic signal, that would be aliased in the reconstructed phase by the tomographic reconstructor. These aberrations are absorbed by the NCPA compensation, however, any drift in these aberrations, or in the online centroid gain estimation will lead to static or quasi-static shapes on the output science images. Such static shapes are often seen on the science PSFs, and we estimate their contributions to be \(\sim 50\) nm rms. To reduce this error, an improved optical design would have included a calibration source at the LGSWFS focal plane, in order to properly calibrate these aberrations. This is however not feasible with the current LGSWFS hardware.

(iv) TT loop frame rate. With the current Real Time Computer (RTC) architecture, the TT loop frame rate can only be an integer of the LGS frame rate. However, and because the LGS photon return is under specification, the TT frame rate is often limited by the LGS one. In other words, there are constellations of bright NGS for which the TT loop could be run faster than the LGS one. This may explain some of the discrepancies seen between PDR and actual performance of the NGS loop reported in Table 2.

(v) TA loop. As explained in Paper I – section 5.3.5, the TA loop cannot be closed for programmes requiring telescope offsets larger than 10 arcsec. Based on simulations, we have estimated that closing the TA loop brings a gain of \(\sim 3\) per cent in \(H\) band.

4.4.4 NGSWFS limiting magnitude

Another major issue in the current state of GeMS is the NGSWFS limiting magnitude. Due to alignment issues and design flaws, the current limiting magnitude achievable with the system is \(m_R < 15.5\). We have estimated the sky coverage achievable by GeMS by running random pointings on the portion of the sky reachable from Gemini South. Assuming a limiting magnitude of \(m_R = 15.5\), we find that the probability of having three GSs or more is 30 per cent, while the probability to have no GS at all is 35 per cent. Pushing the limiting magnitude to \(m_R = 18.5\) (which should be the case after the NGSWFS upgrade, see Section 6.3.1), 72 per cent of the random pointings have three NGS, and only 8 per cent have no GS at all. In that case, the map in Fig. 10 shows how the fields are distributed in the sky.

5 OPERATIONS

Despite its complexity, GeMS can be operated by a crew of only two people: the telescope operator manages all of the AO systems (on top of the telescope), while the laser operator is in charge of the laser and the BTO. The instruments are separate and are operated by the observer.

5.1 GeMS SMART tools and MOP

In GeMS, there are as many as 20 loops and offloads that must be closed, monitored and controlled. A set of dedicated tools have been developed to assist the operators in this task. The first one is called MOP, for the MYST Operational Panel (MOP). MOP has been designed to simplify the interaction with the AO system and integrate automation in the operation flow, assisting the operator.

\(^3\) MYST stands for MCAO Yorick Smart Tools.
both in the acquisition procedure and during the observation. For this, MOP gathers a limited number of possible top-level actions and status of the system in a single screen. If needed, access to low-level screens and status can be done via MOP. The SMART tools have been designed to manage the interactions between the AO system and the telescope control system. As an example, when the operator wants to close the high-order loop, a set of conditions and commands are first executed by the SMART tools: the flux is checked, low-level loops are closed, default matrices are loaded. Once the high-order loops are closed, the SMART tools continue to monitor the status and performance of all loops and can even make decisions (hopefully smart) and take actions according to the external conditions to maintain optimal performance. Optimization of the loops is not done as a background process, but should be triggered by the operator thought MOP. This scheme was selected in order to provide more robustness to system operation.

5.2 Acquisition sequence and overheads

The multiplicity of GeMS WFSs inevitably leads to a rather complex and lengthy acquisition procedure. From the telescope slew to the beginning of the science exposure, the acquisition consists in six main steps. These steps, executed by the laser and the telescope operators, have been detailed in Neichel et al. (2012a). The overall acquisition overheads are ranging from 10 to 30 min, with an average of 20 min. For reference, the overheads associated with ALTAIR, the Gemini North SCAO system are 15 min in average. Most of the acquisition overheads are linked to the NGS acquisition, mainly due to the fact that the NGSWFS probes have only a 1.5 arcsec FoV. Hence for bright NGs, in relatively sparse fields and with little catalogue errors, the full GeMS acquisition can be as fast as 10 min. For faint NGs, or more complex objects (high background or a crowded field) the acquisition procedure can take over 30 min. The upgraded NGSWFS proposed in Section 6.3.1 will greatly improve the NGs acquisition time.

5.3 Dither and sky sequence

A science observation sequence can include telescope offsets for image dithering or sky calibration, or filter changes. For all of these events, specific GeMS loops must either be paused or opened, and then resumed automatically after the event. This is handled by the SMART tools. The sequence of events for each case is described below.

5.3.1 Dither sequence

When a telescope offset is required, the observation sequence executor (SeqExec) sends the information to the telescope control system, that immediately sends it to the SMART tools. All the NGS loops and dependences are then paused (TT, TA, rotator and focus), while all the laser loops are kept closed. The telescope then offsets, and once all the subsystems report that they are in position, the NGS loops are resumed, and the next science exposure starts. Depending on the size of the offsets, a telescope dither can take between 3 and 30 s. The dither pattern is set by the NGS acquisition fields and cannot be larger than 30 arcsec.

5.3.2 Sky sequence

A sky sequence is somewhat similar to a dither, except that the telescope offset is usually much larger (up to 5 arcmin). In this case, all NGS loops and dependences are paused, and the probes are frozen and do not follow telescope offsets (as a large offset would put the probes into a hard limit if they remained in follow). We found that large telescope motions could create instabilities in the high-order loop, as the LGS may be lost for a few seconds. Because of this, the high-order loop is also paused, but the LGS stabilization loop is kept closed (FSA loop). An overhead of 60 s must be accounted for.

5.3.3 Large telescope offsets

If the observation requires offsets larger than 5 arcmin from the base position, the laser propagation must be stopped due to Laser Clearing House (LCH) restrictions (see Section 5.4.1). When the telescope returns to the original base position, the laser operator must re-acquire the LGS. Moreover, since this offset will also be unguided, the telescope operator must re-check the NGS acquisition and correct for any telescope pointing errors. In this case a separate observation block is required and extra overheads are introduced.

5.4 Observation interruptions

5.4.1 LCH predictive avoidance

To prevent any laser illumination of sensitive satellite optics, all laser targets must first be pre-approved by the United State space command LCH. A week before a laser run, Gemini provides the coordinates of each target and receives in return a file from the LCH showing the allowed observation windows for this target. To maximize time on-sky and minimize any potential for inadvertent illumination, an automatic software that handles the laser shutters based on the LCH data has been developed. Only the LGS-related loops are affected. NGS loop and its dependences do not need to be paused. The current overheads associated for a LCH window are of the order of 30 s to 1 mn and also depend on the phasing of the window with the observation sequence.

5.4.2 Aircraft avoidance

In the case of an aircraft passing within 25° of the laser propagation area, the same procedure of pause/resume as the LCH windows is used, except that in this instance the laser operator must manually pause the laser propagation. While an isolated aircraft event will have a larger overhead due to the time required for an aircraft to pass through the safety zone, overall aircraft avoidance overheads are only a factor of 1.3 times larger than satellite overheads as there are fewer aircrafts passing near the propagation zone than satellites.

5.5 Elevation and weather limitations

They are several limitations imposed by GeMS in terms of operations. The main ones are listed below.

5.5.1 Limitation in elevation

The elevation range accessible by GeMS goes from 40° to 85°. This limitation is imposed by the LGSWFS zoom mechanism, which cannot mechanically keep the LGS in focus for elevations higher than 85° or lower than 40°. In addition, the LGS return flux decreases significantly at high airmass which also affects the performance. Objects that transit near to zenith also impose a limitation. The
speed at which the laser constellation can rotate is limited by the rotation speed limit of the BTO KM. For instance, for an object transiting at a peak elevation of 80°, the ‘dead zone’ spans ±2 min about transit.

5.5.2 Clouds and high wind

Because of safety concerns, the laser cannot be propagated in clouds that could hide planes from the laser spotters. The laser can be propagated in thin cirrus, however these cirrus will reduce the laser photon return and affect the AO performance. High winds buffeting the telescope will create wind shake and can jeopardize the TT loop stability. We found that the TT loop could survive with wind on the secondary of up to 2.5–3.0 m s⁻¹.

5.6 Integration with the observatory tools

The Gemini OBSERVING TOOL (ot) is the software used to define the instrument configuration and pre-plan the observations from approved proposals.

To provide the users with a quantitative selection criteria for the required NGSs, an automatic algorithm called MASCOT has been implemented in the ot (Trancho et al. 2008). This algorithm finds the best asterism⁴ of three stars in the group of N stars located inside the NGS patrol field of a specific science field (Ellerbroek & Rigaut 2001; Flicker & Rigaut 2002). We define here best asterism as the asterism that will provide the highest and most homogeneous correction level over the science FoV. The algorithm can also handle suboptimal cases, for example, it can return the best two-star asterism if a three-star asterism is not available. Finally, the user can also overwrite the MASCOT output, and select manually the GSs to use for a given observation.

The selected asterism can be visualized in the ot position editor. Fig. 11 shows an example for the NGC1851 field. The three selected NGS stars are marked as a small green square, and labelled as Canopus WFS (CWFS) 1 to 3. The flexure star, which in that case is a GSAOI ODGW star (see Section 6.2.2), is also marked with a green square, and labelled ODGW2, as the star falls in quadrant 2 of GSAOI. The average SR and FWHM, as well as the variation over the field, calculated using the MASCOT algorithm, are shown at the bottom of the position editor. Predicted iso-Strehl contours are shown as narrow curved green/yellow lines.

6 THE FUTURE OF GEMS

It is expected that GeMS will be in regular operation, as a facility instrument, in 2013 November. The first mode of operation offered is to combine GeMS with GSAOI. More instruments should be commissioned with GeMS in the following semesters. In addition, there are a number of items that have not been commissioned yet, and will possibly be in the near future. Finally, it is planned to improve GeMS performance and address the issues discussed in Section 4.4. These upgrades will be implemented as they become available.

6.1 New science capabilities

6.1.1 GeMS + Flamingos II

Flamingos-2 (F2; Gemini Multi-Object Spectrograph, GMOS; Elston et al. 2003) is a NIR imager, long slit and Multi-Object Spectrograph (MOS). The main scientific interest of GeMS+F2 being the MOS mode, as GSAOI already provides the imaging capability. F2 has been designed to work both in seeing limited, and diffraction limited mode. When used in conjunction with GeMS, it has a 0.09 arcsec pixel scale, and covers a 2 arcmin FoV. The commissioning of GeMS+F2 should start in the course of 2014.

6.1.2 GeMS + GMOS

During the commissioning of GeMS, we had the opportunity to obtain data with the GMOS (F2; Hook et al. 2004) in 2012 March and May. GMOS is a spectroimager working in the visible. In its spectrograph mode, long slit, multislit and one integral field unit are available. The imaging FoV of GMOS through GeMS covers an unvignetted field of 2.5 arcmin², with a pixel scale of 35.9 milliarcsec. The three CCD chips form a 6144 × 4608 pixel array, with two gaps of about 37 pixels separating the detectors. With GeMS, only the reddest GMOS filters can be used. These are the i band (706–850 nm), CaT band (780–933 nm) and z band (≥848 nm). A first analysis of the performance delivered by GeMS/GMOS is presented in Hibon et al. (2013). Although it was not originally intended to offer the GeMS/GMOS combination, it is now planned to open this mode in the future semesters.

⁴A prominent pattern or group of stars that is smaller than a constellation. Oxford dictionary.
6.2 Missing commissioning items

6.2.1 Atmospheric dispersion compensators

Canopus has two atmospheric dispersion compensators (ADCs). One is located on the science path, and can be inserted or removed from the path, the other one is in the NGSWFS path, and is always in. None of these ADCs have been commissioned yet. The current strategy for the NGS ADC will be to set it at the beginning of an observation based on the average telescope elevation, and then keep it fixed to avoid pupil wandering in the SFS path. In the worst case of an observation spanning from Zenith to 40° elevation, the maximum relative elongation due to atmospheric dispersion is ±0.3 arcsec for optical wavelength (550 to 850 nm). The impact on the SNR is then small compared to the complexity of having this ADC in follow mode. The science ADC will be commissioned along with the coupling of GeMS with Flamingos-2.

6.2.2 Flexure loop

The flexure loop uses the signal coming from an On-Instrument WFS to compensate for potential differential flexure between the AO bench and the instrument. The flexure signal is used as soon as the TT loop is closed by moving the three TT WFS probes all together. As the TT loop is closed on the signal coming from these probes, moving the probes moves the TTM accordingly, and results in image motion at the science detector level. First results obtained on-sky have shown that the differential flexures between the AO bench and (for instance) GSAOI are small. We measured image motion of the order of 0.2 arcsec on-sky for 30° elevation steps. Taking into account that the longest exposure time used with GSAOI are of the order of 5 min (to avoid saturation by sky background), we computed that the maximal SR loss due to flexure during a single exposure could never be greater than 1 per cent at H band. Hence, the flexure correction, although tested during commissioning, has never been implemented in the operational scheme. The gain provided was too small compared to the complexity it entailed. When using with Flamingos-2, and because the exposure times will increase, this assessment might change.

6.2.3 ODGW fast guiding

When using GeMS with GSAOI, the ODGWs can be used in a fast read out mode, providing the TT information based on the centroid position of the stars. This mode is particularly interesting for targets embedded in dust, where NIR stars are more easily achievable than the visible ones. In this mode, one visible star (the Canopus probe C3) is still needed for slow focus compensation. This mode has been successfully tested during the commissioning, however has not yet been integrated into operation. It will be offered if enough scientific programmes require it.

6.3 System upgrades

6.3.1 NGSWFS

As explained in Paper I – section 5.3.4, the current NGS WFS has a very low sensitivity. A dedicated attempt to fix the design has been unsuccessful. A project is currently under way at the ANU to build a replacement for the TT NGS WFS, based on a single focal plane array covering the whole 2 arcmin FoV, reading out at 400Hz with less than 2 electrons read out noise. This will boost significantly the TT WFS performance; nominally back to the expected level (limiting magnitude of 18.5). It will also drastically ease the acquisition procedure, and the need for lengthy probe mapping calibrations. Finally, it should provide a solution to the distortion issue discussed in Paper I (section 5.3.5). The new NGSWFS is currently build at ANU, and should be commissioned at Gemini towers by the end of 2014.

6.3.2 DM4.5

The replacement for DM0 should arrive in the first half of 2014, and should be re-integrated in Canopus during the same year.

6.3.3 Laser

The 589 nm Lockheed Martin Coherent Technologies laser is relatively stable at about 42 to 45 W, which is adequate for the high sodium season but significantly limits performance at other times. It is also quite demanding in term of maintenance. Although there is no definite plan, there has been discussions of a possible upgrade. This might be especially timely considering new technologies like Raman lasers (Feng, Taylor & Calia 2009) or optically pumped semiconductor lasers (Berger et al. 2012).

6.3.4 RTC

The RTC has been generally quite reliable. However, it is an ageing piece of equipment (about 10 years old) and as noted in Paper I, cannot accommodate a Pseudo-Open-Loop control model which would certainly improve both performance and stability. An upgrade of the RTC is thus desirable. However, such an upgrade would entail both new hardware and new software, and will inevitably be a major and expensive endeavour. There is no current official plan to replace the RTC.

6.3.5 Laser beam quality

The 50 W laser beam shape, depending on the alignment, can vary from run to run. It is often out of specification in terms of beam quality ($M^2$), which result in larger or aberrated laser spots on the sky, and reduces the SNR on the LGS WFS measurements. Andrés Guesalaga from the Pontificia Universidad Católica de Chile and his team are currently building a two-DM system to remedy that situation. This system should allow them to improve significantly the laser beam quality and is to be inserted in the BTO (Béchet et al. 2013). It should be tested in 2015.

6.3.6 Astrometry calibration

As discussed in Section 4.3, the current astrometric performance is limited by the large amount of quasi-static distortions present in the science path. A possibility to improve the astrometric calibration could be to add a diffractive grid in the optical path, which will generate a grid of diffracted ‘stars’ from the primary target star (see Bendek et al. 2012; Guyon et al. 2012; Ammons et al. 2013). These stars will be numerous enough to fit and remove changing optical distortion. A proposal has been submitted to develop such a hardware solution for GeMS. Funding is currently under investigation.
7 CONCLUSION

GeMS has proven to be an exciting and challenging project. Because many complex subsystems must work in unison, GeMS imposes a level of complexity rarely found in an observatory facility instrument. The amount of time on-sky (about 100 nights) for commissioning activity and work towards the transition into regular operations is testament alone to the complexity of the system. Operating such a complex instrument is also a challenge for the Gemini observatory and a dedicated effort had been put in place in order to simplify and stream-line operations.

GeMS is also a pathfinder instrument, paving the way for the future developments of such systems. It is important to emphasize that no show stoppers have been found on the way, although the delivered performance differs from what was predicted during the design phases. The compensation performance is currently limited by servo lag, noise and generalized fitting, but other, and unexpected terms are also affecting the performance. Furthermore, several calibrations designed during the early phase of the project proved to be either not working or suboptimal during the commissioning, and new solutions had to be developed. As discussed in this paper, work is continuing on the system to improve on all these aspects, as well as many others.

But if GeMS is complex, is it also a rewarding instrument. The programmes executed to date and associated images have already demonstrated its huge and unique scientific potential. Images with FWHM of 0.08 arcsec or better over the 85 arcsec × 85 arcsec FoV are typically obtained under median seeing or better.

ACKNOWLEDGEMENTS

GeMS was a large instrumentation project. In the course of the last 13 years, it involved people from many different disciplines. The authors would like to recognize the contribution and thank Claudio Arraya, Corinne Boyer, Fabian Collao, Paul Collins, Felipe Daruich, Herman Diaz, Matt Doolan, Brent L. Ellerbroek, Aurea Garcia-Rissmann, Fred Gillett, Alejandro Gutierrez, Mark Hunten, Stacy Kang, Matteo Lambini, Bryan Miller, Matt Mountain, Rolando Rogers, Roberto Rojas, Jean-René Roy, Michael Sheehan, Doug Simons, Jan van Harmelen and Shane Walker.

The MASCOT algorithm has been developed in collaboration with Damien Gratadour from Observatoire de Paris.

Part of this work has been funded by the French ANR programme WASABI – ANR-13-PDOC-0006-01.

Based on observations obtained at the Gemini Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under a cooperative agreement with the NSF on behalf of the Gemini partnership: the National Science Foundation (USA), the National Research Council (Canada), CONICYT (Chile), the Australian Research Council (Australia), Ministério da Ciência, Tecnologia e Inovação (Brazil) and Ministerio de Ciencia, Tecnología e Innovación Productiva (Argentina).

In memory of Vincent Fesquet, GeMS’ optical and laser engineer and our friend.
