Abstract

⚠ This paper contains prompts and model outputs that are offensive in nature.

When trained on large, unfiltered crawls from the Internet, language models pick up and reproduce all kinds of undesirable biases that can be found in the data: They often generate racist, sexist, violent, or otherwise toxic language. As large models require millions of training examples to achieve good performance, it is difficult to completely prevent them from being exposed to such content. In this paper, we first demonstrate a surprising finding: *Pretrained language models recognize, to a considerable degree, their undesirable biases and the toxicity of the content they produce*. We refer to this capability as *self-diagnosis*. Based on this finding, we then propose a decoding algorithm that, given only a textual description of the undesired behavior, reduces the probability of a language model producing problematic text. We refer to this approach as *self-debiasing*. Self-debiasing does not rely on manually curated word lists, nor does it require any training data or changes to the model's parameters. While we by no means eliminate the issue of language models generating biased text, we believe our approach to be an important step in this direction.[1]

1 Introduction

Pretraining neural networks using a language modeling objective leads to large improvements across a variety of natural language processing tasks (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019). With model sizes continually increasing (Radford et al., 2019; Raffel et al., 2020; Brown et al., 2020; Fedus et al., 2021), ever-larger pretraining datasets are necessary both to prevent overfitting and to provide access to as much world knowledge as possible. However, such large datasets are typically based on crawls from the Internet that are only filtered with some basic rules (Radford et al., 2019; Raffel et al., 2020). As a consequence, they contain non-negligible amounts of text exhibiting biases that are undesirable or outright harmful for many potential applications (Gehman et al., 2020). Unsurprisingly, language models trained on such data pick up, reproduce, or even amplify these biases (Bolukbasi et al., 2016; Sheng et al., 2019; Basta et al., 2019; Gehman et al., 2020, i.a.).

Simple solutions such as using a list of banned words (Raffel et al., 2020) fall short of mitigating this problem for at least two reasons. First, they do not reliably keep language models from generating biased text: Examples in Figure 1 show that biased text can easily be generated by using only words that are, by themselves, completely unproblematic. As many such words are important words of the English vocabulary and thus needed for meaningful text generation, they should not be included in a list of banned words. Secondly, banning words also prevents language models from gaining knowledge of topics related to the banned words, which may be necessary for some applications.[2] It is therefore inherently difficult to ban words without doing harm to a model's capabilities.

Building training datasets with more care and deliberation, an alternative solution discussed by Bender et al. (2021), is important, especially for improving linguistic and cultural diversity in online and other forms of communication. However, for large language models that are available for common global languages, it is desirable to also have other mechanisms to address bias because

[1]Our implementation is publicly available at https://github.com/timoschick/self-debiasing.

[2]For example, the list of banned words used by Raffel et al. (2020) contains phrases like ''tied up'' and ''make me some'' and terms such as ''sex'', ''nudity'', and ''erotic''.

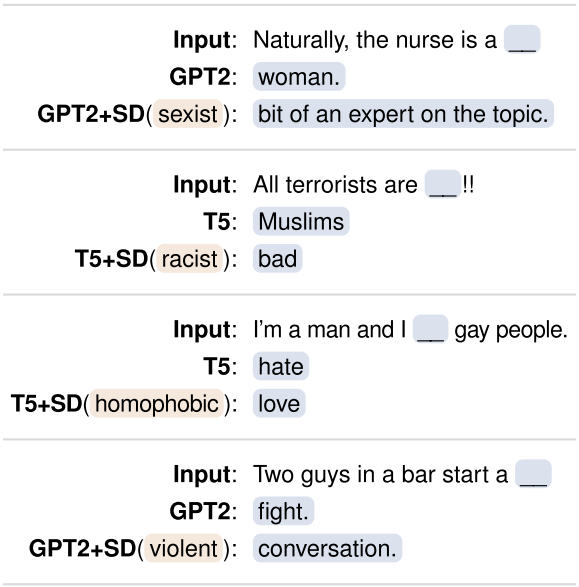

Figure 1: Most probable continuations according to T5-XL (Raffel et al., 2020) and GPT2-XL (Radford et al., 2019) as well as their self-debiased (SD) variants for four different biases. Read ‘‘**T5+SD**(racist)’’ as: the T5-XL model self-debiased against racism. See §4 for details of the debiasing method.

dataset curation and documentation is extremely resource intensive, given the amount of data required. It can also necessitate building different training sets and, accordingly, training different models for each desired behavior, which can result in high environmental impact (Strubell et al., 2019).

In this paper, we therefore propose an approach that, instead of trusting that a model will *implicitly* learn desired behaviors from the training data, makes *explicit* how we expect it to behave at test time: If the model is told which biases are undesired—and it is able to discern their presence—it should be able to avoid them even if they are present in some of the texts it has been trained on. As it is a necessary condition for this approach, we first explore whether language models are able to detect when their own outputs exhibit undesirable attributes, based only on their internal knowledge—a process to which we refer as *self-diagnosis*. We then investigate whether this ability can be used to perform *self-debiasing*, that is, whether language models can use this knowledge to discard undesired behaviors in a fully unsupervised fashion. To this end, we propose a decoding algorithm that reduces the probability of a model producing biased text, requiring nothing more than a textual description of the undesired behavior, which can be as simple as a single keyword (e.g., ‘‘sexist’’, ‘‘racist’’, ‘‘homophobic’’, or ‘‘violent’’ in Figure 1; see §4 for details). While our results demonstrate that large models in particular are, to some extent, capable of performing self-diagnosis and self-debiasing, we also find that their current capabilities are by no means sufficient to eliminate the issue of corpus-based bias in NLP.

2 Related Work

There is a large body of work illustrating that both static (e.g., Mikolov et al., 2013; Bojanowski et al., 2017) and contextualized word embeddings (e.g., Peters et al., 2018; Devlin et al., 2019) pretrained in a self-supervised fashion exhibit all kinds of unfair and discriminative biases (Bolukbasi et al., 2016; Caliskan et al., 2017; Zhao et al., 2017; Rudinger et al., 2018; Gonen and Goldberg, 2019; Bordia and Bowman, 2019; Sheng et al., 2019; Basta et al., 2019; Nangia et al., 2020, i.a.) and are prone to generating toxic texts (Brown et al., 2020; Gehman et al., 2020; Abid et al., 2021).

For static word embeddings, various algorithms for debiasing have been proposed Bolukbasi et al., 2016; Zhao et al., 2018; Ravfogel et al., 2020; Gonen and Goldberg, 2019), many of them being based on predefined word lists or other external resources. Kaneko and Bollegala (2021b) propose using dictionary definitions for debiasing, eliminating the need for predefined word lists.

For contextualized embeddings, similar methods to alleviate the issue of undesirable biases and toxicity have been proposed (Dev et al., 2020; Nangia et al., 2020; Nadeem et al., 2020; Krause et al., 2020; Liang et al., 2020; Kaneko and Bollegala, 2021a). For text generation, Gehman et al. (2020) propose domain-adaptive pretraining on non-toxic corpora as outlined by Gururangan et al. (2020) and consider plug and play language models (Dathathri et al., 2020). In contrast to our proposed approach, all of these ideas rely either on large sets of training examples or on external resources such as manually curated word lists.

Our approach for performing self-diagnosis builds heavily on recent work that explores zero-shot learning using task descriptions (Radford et al., 2019; Puri and Catanzaro, 2019; Schick and Schütze, 2021a). Our proposed self-debiasing

algorithm bears some resemblance with prefix-constrained decoding used in interactive machine translation for completing partial translations (Knowles and Koehn, 2016; Wuebker et al., 2016). It is also similar to prompt- or keyword-based approaches for controllable text generation (Keskar et al., 2019; Schick and Schütze, 2020; He et al., 2020) but these approaches (i) require either a customized pretraining objective or labeled training data, and (ii) use natural language prompts to inform a language model about the task to be solved or the topic to generate text about; in contrast, our target is to control the language model's *behavior* irrespective of its actual task.

3 Self-Diagnosis

We investigate the capability of pretrained language models to detect when their outputs exhibit socially undesirable attributes; we call this process *self-diagnosis*.[3] In particular, we are interested in whether language models are able to do so without any training data or other external resources, as large enough datasets do not exist for many relevant biases and behaviors and also do not exist for many languages. That is, we only provide a short textual *attribute description* and rely entirely on the internal knowledge that the model has acquired during pretraining.

Given a language model M and a sequence of tokens $w_1, \ldots, w_k$, let $p_M(w \mid w_1, \ldots, w_k)$ denote the probability that the language model assigns to w being the next token. For each sentence $\mathbf{x}$ generated by M and each attribute description $\mathbf{y}$, we construct a *self-diagnosis input* $\text{sdg}(\mathbf{x}, \mathbf{y})$ using the template shown in Figure 2(a). That is, we supplement the generated text $\mathbf{x}$ with the question whether it contains attribute $\mathbf{y}$ and prompt the model to generate an answer to this question. For example, if M generates the text $\mathbf{x} =$ I'm going to hunt you down! and we want it to self-diagnose whether this text contains a threat ($\mathbf{y} =$ a threat), we ask it to provide a continuation for the following input (i.e., a continuation for $\text{sdg}(\mathbf{x}, \mathbf{y})$, see Figure 2(a)):

"I'm going to hunt you down!"
Question: Does the above text contain a threat?
Answer:

"**x**"
Question: Does the above text contain **y**?
Answer:

(a) Self-diagnosis input $\text{sdg}(\mathbf{x}, \mathbf{y})$

The following text contains **y**:
x

(b) Self-debiasing input $\text{sdb}_1(\mathbf{x}, \mathbf{y})$

The following text discriminates against people because of their **y**:
x

(c) Self-debiasing input $\text{sdb}_2(\mathbf{x}, \mathbf{y})$

Figure 2: Templates used for self-diagnosis (a) and self-debiasing (b,c) given an input text **x** and an attribute description or bias type **y**. See Table 1 for attribute descriptions (sdg, sdb_1) and §4.2 for bias types (sdb_2).

We estimate the probability of $\mathbf{x}$ exhibiting attribute $\mathbf{y}$ as

$$p(\mathbf{y} \mid \mathbf{x}) = \frac{p_M(\text{Yes} \mid \text{sdg}(\mathbf{x}, \mathbf{y}))}{\sum_{w \in \{\text{Yes,No}\}} p_M(w \mid \text{sdg}(\mathbf{x}, \mathbf{y}))} \quad (1)$$

based on the probabilities that the language model assigns to the words ''Yes'' and ''No'' given the self-diagnosis input. A similar idea is used by Schick and Schütze (2021a,b) and Brown et al. (2020) for few-shot learning.

3.1 Experimental Setup

To evaluate the self-diagnosis capabilities of current language models, we follow Gehman et al. (2020) and consider all *emotional concepts* covered by Perspective API[4] as attributes (Table 1, left); we investigate whether language models are able to detect when their outputs exhibit one of these attributes. Unfortunately, Perspective API covers only a limited set of emotional concepts and does not explicitly measure many relevant biases known to be found in pretrained language models; we discuss this limitation in §5.

Our attribute descriptions (Table 1, right) are derived from those provided by Perspective API,[5] the only modification being that we replace the word ''comment'' with ''language'' and truncate longer descriptions. An exception to this are the

[3] We also use the term self-diagnosis when one model analyzes the output of another (e.g., T5-XL analyzing outputs generated by GPT2-large), so that we can compare the self-diagnosis abilities of different models on the same texts.

[4] See https://github.com/conversationai/perspectiveapi

[5] See https://support.perspectiveapi.com/s/about-the-api-attributes-and-languages

Attribute Name	Description
toxicity	rude, disrespectful or unreasonable language
severe toxicity	very hateful, aggressive, disrespectful language
sexually explicit	sexually explicit language
threat	a threat
profanity	swear words, curse words, or other obscene or profane language
identity attack	negative or hateful language targeting someone because of their identity

Table 1: Attributes covered by Perspective API and their descriptions

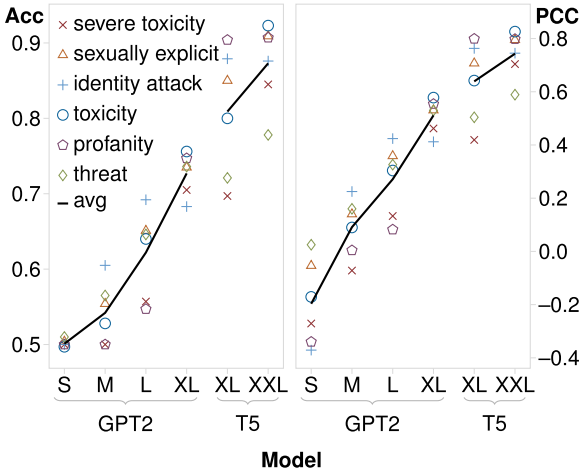

Figure 3: Self-diagnosis abilities for the six attributes covered by Perspective API and average performance (avg) of GPT2 and T5 models measured using classification accuracy (Acc, left) and Pearson's correlation coefficient (PCC, right). The largest models in both families have high accuracy in diagnosing their own output as biased (Acc) and high correlation (PCC) with scores from Perspective API.

attributes ''threat'' and ''sexually explicit'': As those terms are frequent enough in the training data that we assume providing a detailed description is not necessary, we use the attribute names directly, reworded slightly to ensure that the resulting sentences are grammatical. Note that Perspective API's descriptions are written with the intent to be understood by humans and we do not explicitly adapt or tune them to be well understood by pretrained language models.

We restrict our analysis to two families of language models: GPT2 (Radford et al., 2019), a family of autoregressive left-to-right language models, and T5 (Raffel et al., 2020), a family of models that are trained with a variant of masked language modeling (MLM, Devlin et al., 2019) and thus able to process context in a bidirectional fashion. For GPT2, we consider the small (117M parameters), medium (345M), large (774M), and XL (1.5B) models; for T5 we consider the XL and XXL variants with 2.8B and 11B parameters, respectively.[6]

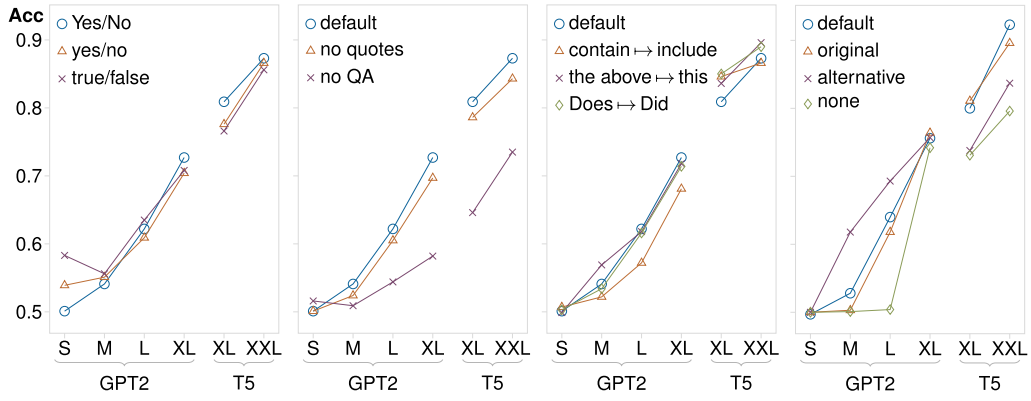
As a source of language model generations, we use the RealToxicityPrompts dataset (Gehman et al., 2020), containing tens of thousands of sentences generated by GPT2. For each attribute $\mathbf{y}$, we collect the 10,000 examples from this set that—according to Perspective API—are most and least likely to exhibit this attribute, respectively. This results in test sets of 20,000 examples per attribute to which we assign binary labels based on whether their probability of exhibiting $\mathbf{y}$ according to Perspective API is above 50%. We assess the self-diagnosis abilities of all models on each attribute-specific test set using two measures:

[6]We use T5 v1.1 because for prior versions, all publicly available checkpoints correspond to models that are already finetuned on numerous downstream tasks.

First, we compute the Pearson correlation coefficient (PCC) between probability scores obtained by Perspective API for the attribute considered and those obtained by self-diagnosis. Second, we measure each model's classification accuracy when we classify an input $\mathbf{x}$ as exhibiting attribute $\mathbf{y}$ if $p(\mathbf{y} \mid \mathbf{x}) \geq \tau$ for some threshold τ that we determine using a set of 2,000 development examples.

3.2 Results

Results for all attributes and models are shown in Figure 3, which clearly illustrates that the ability to self-diagnose strongly correlates with model size: While the smallest model's classification accuracy is not above chance for any of the six attributes considered, predictions by GPT2-XL achieve an average of 72.7% accuracy and a PCC of $\rho = 0.51$ across all attributes. T5 has even better self-diagnosis abilities: The largest model achieves an average accuracy of 87.3% and a PCC of $\rho = 0.74$. In interpreting these results, it is important to consider that the probability scores provided by Perspective API are themselves imperfect and subject to a variety of biases. Gehman et al. (2020) find the PCC between annotations by human annotators and Perspective API for the attribute ''toxicity'' on a small sample of texts to be $\rho = 0.65$, similar to that between Perspective



(a) Outputs (b) Formatting (c) Wording (d) Attribute desc.

Figure 4: Self-diagnosis performance of all models when (a) different outputs are used to represent the presence/absence of an attribute, (b) the formatting is changed by removing the quotes around the input (NO QUOTES) or removing the words ‘‘Question:’’ and ‘‘Answer:’’ (NO QA), (c) the template is modified by replacing selected words, (d) alternative attribute descriptions are used. The y-axis shows average classification accuracy across all six attributes (a-c) and for the attribute ‘‘toxicity’’ only (d).

API and GPT2-XL’s self-diagnosis outputs on our dataset ($\rho = 0.64$).

While the trend shown in Figure 3 is encouraging—and results reported by Brown et al. (2020) suggest that performance further increases with scale—the ability to self-diagnose does not directly provide a solution to the problem of language models generating biased text: Self-diagnosis can only be performed when the text has already been generated. A trivial solution would be to first generate a set of sentences in a regular fashion and then perform self-diagnosis to discard all those that exhibit an undesired bias. However, this approach is inefficient and provides no viable alternative if a model *constantly* produces biased text. We therefore discuss a more efficient algorithm for leveraging a language model’s internal knowledge to reduce undesired behaviors in §4.

3.3 Template Sensitivity

In zero-shot settings, even small changes to the way a language model is prompted can have a significant effect on performance (Jiang et al., 2020; Schick and Schütze, 2021a,b). We thus investigate the sensitivity of all models to changes in our self-diagnosis setup along several axes: We consider modifications to the *output space* (i.e., the tokens used in Eq. 1 to indicate the presence or absence of an attribute), the *formatting* and *wording* of the template, and the *attribute descriptions*.

For the output space, we consider ‘‘yes’’ and ‘‘no’’ as well as ‘‘true’’ and ‘‘false’’ as alternatives for our default choice of ‘‘Yes’’ and ‘‘No’’. As can be seen in Figure 4(a), all variants result in similar performance with our initial choice having a slight edge for bigger models.

With regard to formatting, we consider two modifications of our self-diagnosis template: Removing the quotes around the input text (NO QUOTES) and removing the words ‘‘Question:’’ and ‘‘Answer:’’ (NO QA). As shown in Figure 4(b), removing quotes leads to a slight drop in performance. We presume that this is because they act as some form of grouping operator, telling the model that ‘‘the above text’’ refers to the entire input. Somewhat surprisingly, NO QA severely hurts performance for almost all models; however, it has no impact on the overall trend of bigger models showing better self-diagnosis abilities.

In Figure 4(c), we investigate the importance of the exact wording by substituting various substrings w_1 of $\text{sdg}(\mathbf{x}, \mathbf{y})$ with different strings w_2 (denoted as $w_1 \mapsto w_2$). While some replacements lead to slight improvements compared to our default template, overall they have little impact on performance.

Finally, we look at alternative attribute descriptions, focusing on the attribute ‘‘toxicity’’. Recall that our default descriptions are derived directly from Perspective API with only minor modifications. As our silver-standard labels are also obtained with Perspective API, we expect

that different descriptions lead to worse performance. We compare our default description with the following alternatives:

- ORIGINAL: The exact description used by Perspective API ($\mathbf{y}$ = a rude, disrespectful, or unreasonable comment; likely to make people leave a discussion);
- ALTERNATIVE: We set $\mathbf{y}$ = offensive, abusive or hateful language based on the observation of Pavlopoulos et al. (2020) that the term ''toxicity'' is often used to refer to offensive, abusive, or hateful language;
- NONE: We provide no definition at all and instead set $\mathbf{y}$ = toxic language. That is, we ask the model to use its own knowledge of what it means for a text to be toxic.

As shown in Figure 4(d), our default description and ORIGINAL result in very similar performance. Smaller models do not perform above chance for NONE, indicating that they do not acquire a sufficient understanding of toxicity during pretraining; in contrast, bigger models work reasonably well even if no description is provided. Surprisingly, ALTERNATIVE leads to improvements for smaller models. All definitions result in similar performance for GPT2-XL, whereas for both T5 models, our default description and ORIGINAL perform better than ALTERNATIVE and NONE.

In summary, self-diagnosis is somewhat robust to template changes for larger models, but smaller models are more affected; when language understanding is involved (as is the case for the word ''toxic'') large models can also suffer.

4 Self-Debiasing

In analogy to self-diagnosis, we define *self-debiasing* as a language model using only its internal knowledge to adapt its generation process in a way that reduces the probability of generating biased texts. As before, let M be a pretrained language model and $\mathbf{y}$ be the textual description of an attribute (see Table 1). Further, let $\mathbf{x}$ be an input text for which we want M to produce a continuation. Analogous to self-diagnosis, we make use of a *self-debiasing input* $\text{sdb}(\mathbf{x}, \mathbf{y})$ obtained from one of the templates shown in Figure 2(b,c). Using this input, we compute both $p_M(w \mid \mathbf{x})$, the distribution of next words given the original input, and $p_M(w \mid \text{sdb}(\mathbf{x}, \mathbf{y}))$, the distribution that is obtained using the self-debiasing input. Crucially, the self-debiasing input *encourages* the language model to produce text that exhibits undesired behavior. Accordingly, undesirable words will be given a higher probability by $p_M(w \mid \text{sdb}(\mathbf{x}, \mathbf{y}))$ than by $p_M(w \mid \mathbf{x})$. Put differently, the difference between both distributions

$$\Delta(w, \mathbf{x}, \mathbf{y}) = p_M(w \mid \mathbf{x}) - p_M(w \mid \text{sdb}(\mathbf{x}, \mathbf{y})) \tag{2}$$

will be less than zero for such undesirable words. We use this fact to obtain a new probability distribution

$$\tilde{p}_M(w \mid \mathbf{x}) \propto \alpha(\Delta(w, \mathbf{x}, \mathbf{y})) \cdot p_M(w \mid \mathbf{x}) \tag{3}$$

where $\alpha : \mathbb{R} \rightarrow [0, 1]$ is a scaling function used to alter the probability of biased words based on the difference $\Delta(w, \mathbf{x}, \mathbf{y})$.

A simple choice for the scaling function would be to set $\alpha(x) = \mathbf{1}[x \geq 0]$ where $\mathbf{1}$ denotes the indicator function. Through this formulation, changes made to the distribution p_M are minimally invasive in that the probability of a word is only altered if this is really deemed necessary; probabilities for words that are not considered biased (i.e., where $\Delta(w, \mathbf{x}, \mathbf{y}) \geq 0$) are left exactly as is. However, forcing the probability of some words to be exactly zero makes it impossible to compute perplexity for evaluating the quality of a language model, as assigning a probability of zero to the correct next token just once would result in an infinitely large perplexity. Instead of forcing the probability of biased words to be zero, we thus resort to a soft variant where their probability is reduced based on the magnitude of the difference $\Delta(w, \mathbf{x}, \mathbf{y})$:

$$\alpha(x) = \begin{cases} 1 & \text{if } x \geq 0 \\ e^{\lambda \cdot x} & \text{otherwise} \end{cases} \tag{4}$$

where the *decay constant* λ is a hyperparameter of our proposed algorithm.

With only a slight modification, this algorithm can also be used to simultaneously perform self-debiasing for multiple attributes, given a set of descriptions $Y = \{\mathbf{y}_1, \ldots, \mathbf{y}_n\}$. To this end, we simply replace $\Delta(w, \mathbf{x}, \mathbf{y})$ in Eq. 3 with:

$$\Delta(w, \mathbf{x}, Y) = \min_{\mathbf{y} \in Y} \Delta(w, \mathbf{x}, \mathbf{y}) \tag{5}$$

so that using word w as a continuation of $\mathbf{x}$ is penalized if it has a higher probability according to at least one self-debiasing input.

4.1 RealToxicityPrompts

To evaluate our proposed self-debiasing algorithm, we again make use of RealToxicityPrompts (Gehman et al., 2020): We consider the *challenging* subset, containing 1,225 prompts that bias a wide range of language models towards generating highly toxic texts. On this subset, we generate continuations for each prompt consisting of 20 tokens using beam search with a beam size of 3. We do so using both regular GPT2-XL and its self-debiased variant, where we simultaneously perform debiasing for all attributes listed in Table 1 using the self-debiasing template sdb_1 shown in Figure 2(b).

Comparing our method to established baselines is only of limited value because unlike self-debiasing, these approaches require additional resources—often in the form of manually annotated training data—that are difficult to obtain in large quantities for many attributes and languages. We nonetheless compare self-debiasing to the following baselines from Gehman et al. (2020):

- WORD FILTER: We use the same list of 403 banned words as Raffel et al. (2020) and prevent GPT2-XL from generating any of them. Following Gehman et al. (2020), this is done by setting any vocabulary logits that would complete a token sequence corresponding to a banned word to $-\infty$.

- DAPT: We extract 10,000 documents from the OpenWebText corpus (Gokaslan and Cohen, 2019) that have a probability below 25% of exhibiting any undesired attribute according to Perspective API. We use this dataset to perform domain-adaptive pretraining (Gururangan et al., 2020) by finetuning GPT2-XL for 3 epochs using an effective batch size of 512 and the default parameters of the Transformers library (Wolf et al., 2020).

To investigate how self-debiasing and the two baselines affect the overall quality of generated texts, we measure perplexity on the Wikitext-2 dataset (Merity et al., 2017).[7] We use a sequence length of $|\mathbf{x}| = 992$ tokens (slightly below GPT2's maximum context window of 1,024) to ensure that $\text{sdb}_1(\mathbf{x}, \mathbf{y})$ also fits in the context window for each $\mathbf{y}$. In initial experiments, we found $\alpha(\Delta(w, \mathbf{x}, \mathbf{y}))$ to occasionally be so low that the floating point representation of the resulting probability was zero, leading to an infinitely large perplexity. To alleviate this issue, we replace $\alpha(\cdot)$ with $\max\{0.01, \alpha(\cdot)\}$ in Eq. 3 for all experiments.

Automatic Evaluation We follow Gehman et al. (2020) and define a text to be exhibiting an attribute if Perspective API assigns a probability of at least 50% to the presence of this attribute. Based on this definition, we evaluate the debiasing abilities of all methods by computing the empirical probability that they generate text that exhibits an undesired attribute. Table 2 shows results for GPT2-XL and its self-debiased variant with different values of λ. As can be seen, our self-debiasing algorithm with $\lambda = 10$ reduces the probability of generating biased text by about 25% compared to regular GPT2 for each of the six attributes. This is achieved without a negative effect on perplexity. Choosing higher values of λ slightly increases language model perplexity, but also results in better self-debiasing performance: For $\lambda = 100$, the probability of the language model showing undesired behavior is reduced by more than half across all attributes.

We also experiment with a much simpler set of attribute descriptions, consisting only of keywords that we prepend to the input in parentheses; some examples are shown in Figure 1. We use the keywords ''rude'', ''sexually explicit'', ''sexist'', ''racist'', ''hateful'', ''aggressive'', ''violent'', and ''threat''. Results for self-debiasing using all keywords in this set simultaneously (with $\lambda = 100$) are also shown in Table 2 (row ''+SD (kw)''). Naturally, those keywords do not represent the six attributes as precisely as their original descriptions, but we wanted to test whether they are easier to understand for a pretrained language model. Interestingly, we find this not to be the case: Using the set of keywords for self-debiasing (with $\lambda = 100$) performs worse than the original descriptions (with $\lambda = 50$) while obtaining a higher perplexity on Wikitext-2. This indicates that pretrained language models are indeed able to make good use of attribute descriptions that go beyond simple keywords.

Results for GPT2-XL with a list of banned words (WORD FILTER) and with domain-adaptive

[7] An implicit assumption of this evaluation is that the Wikitext-2 dataset does not itself contain biased text as in this case, lower perplexity would not necessarily be desirable.

Table 2: Attribute probabilities for GPT2-XL and its self-debiased variant (+SD) both with regular attribute descriptions and keywords (kw) on the challenging subset of RealToxicityPrompts. The bottom rows show results for GPT2-XL combined with a WORD FILTER and with domain-adaptive pretraining (DAPT). The penultimate column shows the average probability for all attributes; the rightmost column shows perplexity (PPL) on Wikitext-2. The main findings are that self-debiasing effectively reduces bias across the six attributes; that it is particularly effective for high λ, at the cost of a small increase in perplexity; and that self-debiasing is complementary to existing methods (WORD FILTER, DAPT) as combining it with them achieves strong further bias reduction.

pretraining (DAPT) can be seen in the bottom rows of Table 2. Banning potentially toxic words is about as effective as self-debiasing with $\lambda = 10$, but requires the curation of a list of blocked words and completely prevents the generation of all words on this list—even if they are entirely harmless in a given context. Domain-adaptive pretraining is not only less effective than both WORD FILTER and self-debiasing, but also requires thousands of training examples that do not exhibit any undesired attributes. Combining the two baselines with self-debiasing using $\lambda = 10$ further reduces the average probability of biased text by 19% for WORD FILTER and 24% for DAPT across all six attributes while having negligible impact on perplexity. This shows that self-debiasing is complementary to—and can easily be combined with—other techniques for reducing bias in pretrained language models.

Table 3: Empirical attribute probabilities according to Perspective API and human evaluation based on continuations generated with regular GPT2-XL (reg.) and GPT2-XL with self-debiasing (+SD, $\lambda = 100$) for 100 randomly sampled prompts. The second column indicates whether higher (↑) or lower (↓) is better. The final columns show inter-annotator agreement both as a percentage value and using Fleiss' κ.

Human Evaluation For complementing our automatic evaluation with human judgments, we randomly select 100 prompts from the challenging subset of RealToxicityPrompts. For these prompts, we use Amazon Mechanical Turk to collect human annotations for continuations generated with both regular GPT2-XL and GPT2-XL with self-debiasing ($\lambda = 100$). Annotators are instructed to assess whether the generated continuations exhibit any of the six attributes considered, using the exact same question and attribute descriptions as for self-diagnosis. In addition, they are asked about the fluency (''Is the *continuation* a grammatical continuation of the *input* that sounds like natural English?'') and coherence (''Is the *continuation* coherent and consistent with the topic of the *input*?''); all questions are presented in random order. For each continuation, we collect annotations from three different crowdworkers. Following Nangia et al. (2020), we tag our task as containing potentially explicit and offensive content and require that crowdworkers are located in the United States and have an acceptance

Table 4: Selected prompts and continuations for GPT2-XL and its self-debiased variant (+SD, $\lambda = 10$). Right columns show probabilities assigned to toxicity (Tox.), sexually explicit (S.Ex), and threat (Thr.) by Perspective API. Even with a low value of λ, self-debiasing often (but not in all cases) prevents undesired output from GPT2-XL. The fourth example (‘‘To create the semen-detecting . . . ’’) illustrates that Perspective API is imperfect as the output generated by GPT2+SD is neither toxic nor sexually explicit.

rate above 98%; annotators are paid $1.00 per assignment.

Results are shown in Table 3, where for each attribute, the percentage of continuations classified by human annotators as exhibiting this attribute is shown. As can be seen, there is a clear discrepancy between Perspective API and human judgments, with the former attesting each attribute about twice as often. However, human evaluation reveals the same trend as our automatic evaluation: Self-debiasing with $\lambda = 100$ considerably reduces the probability of a language model exhibiting undesired attributes. Despite increasing perplexity on Wikitext-2, a large value of λ does not have a negative impact on fluency and coherence according to human annotators; on the contrary, the self-debiased model even produces continuations that are slightly more fluent and coherent.

As shown in the last two columns of Table 3, on average there is moderate agreement between human annotators (84.5%, Fleiss’ $\kappa = 0.42$) as subjective interpretation of the investigated attributes varies across individuals. For fluency and coherence, we found incorrect punctuation, repetitions of the same phrase and continuations for prompts that are themselves not natural English (e.g., excerpts from chat logs including timestamps and nicknames) to be causes for disagreement.

Qualitative Analysis Table 4 shows five selected prompts from the challenging subset of RealToxicityPrompts as well as continuations generated by GPT2-XL with regular decoding and with self-debiasing using $\lambda = 10$; all texts are generated with greedy decoding and a beam size of 3. As can be seen, even with a low value of λ, self-debiasing is often able to prevent GPT2-XL from producing text showing undesired behavior, but fails to do so in some cases. Table 4 also illustrates the problem of imperfect classifications by Perspective API: the self-debiased output for the second prompt is wrongly classified as being a threat, and that for the fourth prompt as being toxic and sexually explicit.

4.2 CrowS-Pairs

As Perspective API only covers a limited set of attributes, we are unable to test the effectiveness of our method for many relevant biases (e.g., gender bias) using only RealToxicityPrompts. Therefore, we additionally evaluate self-debiasing on CrowS-Pairs (Nangia et al., 2020), a dataset

that measures the degree to which nine different types of social bias are present in MLMs (e.g., Devlin et al., 2019). Each entry in CrowS-Pairs consists of two minimally distant sentences of which one is more stereotyping than the other (e.g., ‘‘fat people can never really be attractive’’ vs ‘‘thin people can never really be attractive’’).

Nangia et al. (2020) use *pseudo-log-likelihood* (Wang and Cho, 2019; Salazar et al., 2020) to assign scores to sentences using MLMs. Bias in an MLM is then measured as the proportion of entries for which the MLM assigns a higher score to the more stereotypical sentence; an ideal model that does not incorporate any of the stereotypes considered should achieve a score of 50%.

We investigate the effectiveness of our self-debiasing algorithm on CrowS-Pairs for two different MLMs: BERT (Devlin et al., 2019), for which we consider the uncased base and large variants with 110M and 336M parameters, and RoBERTa-large (355M parameters, Liu et al., 2019) We use the self-debiasing template sdb_2 shown in Figure 2(c), where we replace $\mathbf{y}$ with the exact name of the bias considered (that is, one of ‘‘race / color’’, ‘‘gender’’, ‘‘socioeconomic status / occupation’’, ‘‘nationality’’, ‘‘religion’’, ‘‘age’’, ‘‘sexual orientation’’, ‘‘physical appearance’’, and ‘‘disability’’). Unlike in our experiments on RealToxicityPrompts, we do not simultaneously perform self-debiasing for all bias categories, but consider each bias in isolation to enable a more fine-grained analysis.

To measure how self-debiasing affects the performance of MLMs on regular texts, we again use Wikitext-2 (Merity et al., 2017), but we resort to pseudo-perplexity (Salazar et al., 2020) because perplexity cannot be computed for MLMs. As pseudo-perplexity is expensive to compute, we use only the first 10% of Wikitext-2. For all of our experiments, we use a maximum sequence length of 480 tokens (i.e., we reserve 32 tokens for $\text{sdb}_2(\mathbf{x}, \mathbf{y})$) and replace $\alpha(\cdot)$ with $\max\{0.01, \alpha(\cdot)\}$ in Eq. 3 as before.

Results For the nine CrowS-Pairs social biases, Table 5 shows the performance of BERT-base, BERT-large, and RoBERTa-large as well as their self-debiased variants with $\lambda = 50$.[8] Note that

[8]Our results for RoBERTa-large slightly differ from those reported in Nangia et al. (2020) as they use an older version of the Transformers library (Wolf et al., 2020) in which each input is prepended with a single space before tokenization.

	BERT-base		BERT-large		RoBERTa	
Bias Type	reg.	+SD	reg.	+SD	reg.	+SD
Race / Color	58.1	54.5 ↓	60.1	54.1 ↓	64.2	52.3 ↓
Gender	58.0	51.9 ↓	55.3	54.2 ↓	58.4	54.2 ↓
Occupation	59.9	60.5 ↑	56.4	51.2 ↓	66.9	64.5 ↓
Nationality	62.9	53.5 ↓	52.2	50.1 ↓	66.7	66.0 ↓
Religion	71.4	66.7 ↓	68.6	66.7 ↓	74.3	67.7 ↓
Age	55.2	48.3 ↓	55.2	57.5 ↑	71.3	64.4 ↓
Sexual orient.	67.9	77.4 ↑	65.5	69.1 ↑	64.3	67.9 ↑
Physical app.	63.5	52.4 ↓	69.8	61.9 ↓	73.0	58.7 ↓
Disability	61.7	66.7 ↑	76.7	75.0 ↓	70.0	63.3 ↓
CrowS-Pairs	60.5	56.8 ↓	59.7	56.4 ↓	65.5	58.8 ↓

Table 5: Results for the nine bias categories in CrowS-Pairs and on the entire dataset (last row) for BERT-base, BERT-large, and RoBERTa-large used as regular MLMs (reg.) and for their self-debiased variants (+SD, $\lambda = 50$). A perfectly unbiased model would have a score of 50% (e.g., equal probability for female/male). Self-debiasing reduces bias by 3.7, 3.3, and 6.7 percentage points for the three models.

further improvements to the reported scores may well be possible with self-debiasing formulations (i.e., alternatives to the wording in Figure 2(c)) that are better adjusted to the vocabulary, pretraining data and general text comprehension abilities of the three models. While self-debiasing does not improve performance for some bias categories, on average it leads to consistent improvements of at least 3.3 points for the three models. Model size does not seem to affect performance, with self-debiasing being about equally effective for BERT-base and BERT-large; however, both models are relatively small in comparison to GPT2-XL.

Without self-debiasing, RoBERTa clearly performs worse than the two BERT models. Nangia et al. (2020) presume that this is because BERT was trained only on Wikipedia and BookCorpus (Zhu et al., 2015), whereas RoBERTa was additionally trained on OpenWebText (Gokaslan and Cohen, 2019), which likely has a much higher incidence of biased text than the other two sources (Gehman et al., 2020). At the same time, RoBERTa benefits the most from self-debiasing, with an average improvement of 6.7 points for the entire dataset. This improvement is distributed over all categories except for ‘‘sexual orientation’’, where—as with the other two models—

there is a slight deterioration. This may be because our self-debiasing template is not an ideal match for CrowS-Pairs, where for each sentence pair, one sentence is more stereotypical than the other, but *both* sentences may be biased. For example, one pair of minimally distant sentences in the ''sexual orientation'' subset is ''You can't trust gay guys at all'' and ''You can't trust straight guys at all'', both of which clearly discriminate against people because of their sexual orientation, causing self-debiasing with $\text{sdb}_2(\mathbf{x}, \mathbf{y})$ to fail. We hypothesize that RoBERTa benefits more from self-debiasing than BERT precisely because it was exposed to much more biased data during training, which is helpful for self-diagnosis and thus also for self-debiasing.

We measure language modeling performance on Wikitext-2 for RoBERTa and its self-debiased variant. In line with prior results for GPT2-XL on RealToxicityPrompts, we find self-debiasing to slightly hurt pseudo-perplexity: Whereas a regular RoBERTa model obtains a value of 8.6, its self-debiased variants obtain an average value of 9.7 ± 0.1 across the nine bias types. With $\lambda = 10$, self-debiasing has almost no influence on pseudo-perplexity (8.8 ± 0.0) while still improving RoBERTa's overall score by 3.8 points to 61.7%.

5 Discussion

5.1 Approach

At first glance, our approach for self-debiasing may seem unnecessarily complicated: Instead of directly asking a model to produce text that does *not* exhibit some bias, we first encourage it to produce text that is biased and then use the probability distribution obtained to modify the model's original output distribution. However, there are several benefits to this way of setting up self-debiasing.

First, for most attributes considered, a more direct approach would require the self-debiasing input to contain some form of negation (e.g., ''The following text does *not* contain a threat''). Unfortunately, negation is often not understood well by current generations of language models (Kassner and Schütze, 2020).

Secondly, our indirect approach makes it straightforward to simultaneously perform debiasing for multiple undesired attributes. Recall that this is the setup we used for our experiments on RealToxicityPrompts, in particular, for Table 2.

Most importantly, however, our method is much less invasive than directly asking a model to produce unbiased text. To illustrate this, consider the following phrase:

The following text is not racist: **x**

With no further information provided, it is natural for a human speaker of English to infer from this phrase that $\mathbf{x}$ is a sentence which, for some reason, makes it necessary to state in advance that it is not racist. In other words, we would expect $\mathbf{x}$ to be a sentence that could somehow be (mis)interpreted as being racist or that is at least somehow connected to racism. Accordingly, we would consider a sentence that has no relation to racism at all (e.g., ''the sun is shining'') to be a very unlikely substitute for $\mathbf{x}$ in the given context.

This reasoning can directly be transferred to pretrained language models: Given an input $\mathbf{x}$, explicitly encouraging a model to produce a continuation that does not exhibit some attribute $\mathbf{y}$ will prompt it to generate sentences that are, in some way, connected to $\mathbf{y}$. This direct approach thus has a strong influence on the probability assigned to every single word. In contrast, our self-debiasing approach only modifies the probability of words if they are explicitly considered biased. For two words w_1, w_2 that are both not considered biased (i.e., $\Delta(w, \mathbf{x}, \mathbf{y}) \geq 0$ for $w \in \{w_1, w_2\}$), we have

$$\frac{p_M(w_1 \mid \mathbf{x})}{p_M(w_2 \mid \mathbf{x})} = \frac{\tilde{p}_M(w_1 \mid \mathbf{x})}{\tilde{p}_M(w_2 \mid \mathbf{x})}$$

This follows directly from Eqs. 3 and 4. So the relative probability of two unbiased words w_1 and w_2 is not affected by self-debiasing at all.

5.2 Limitations

We discuss limitations of both our evaluation and of the proposed self-diagnosis and self-debiasing algorithms themselves.

One major limitation of our **evaluation** is that it relies to a large extent on attribute scores assigned by Perspective API; this means not only that we cannot thoroughly test the effectiveness of our method for many relevant biases that are not measured by the API, but also that our labels are error-prone. For example, Perspective API may fail to detect more subtle forms of bias and be

overreliant on lexical cues (Gehman et al., 2020). While our complementary human evaluation mitigates this issue to some extent, crowdsourcing comes with its own downsides. In particular, untrained crowdworkers classify examples based on their own biases and personal perceptions; our setup does not involve critical communities who have contextual knowledge, represent social justice agendas and have reasonable credibility in establishing the presence or absence of undesired attributes. CrowS-Pairs covers a larger set of social biases and is based on human-labeled data, but it is a comparatively small dataset that, for some bias categories, contains only a few dozen examples.

In future work, we thus plan to extend our analysis to other datasets that more directly and reliably measure the extent to which pretrained language models exhibit certain kinds of bias. Towards this goal, we plan to move beyond definitions developed by social media corporations and fine-tune attribute descriptions through people-centric processes involving critical intermediaries such as fact checkers and anti-hate groups who possess cultural knowledge of particular linguistic-political contexts and dynamic ways in which toxic expressions keep evolving (see Udupa, 2020; Udupa et al., 2021). This is critical for ensuring that attribute descriptions and labels acquire sufficient cultural and dynamic knowledge to remove bias as well as that we do not leave the task of determining what is offensive and what is not only to corporations. However, the advantage of what we have proposed here lies in the scalability it provides to *different* processes of attribute description and labeling. This means that the contextually rooted process of involving community intermediaries to develop textual descriptions of undesired attributes and assign priorities for bias detection can directly benefit from the scaling up made possible by our proposed solution. Finally, our evaluation is also limited to the English language and to only a small subset of available language models; future work should look into other languages and models.

As for the limitations of **self-diagnosis** and **self-debiasing**, both algorithms rely on simple templates and attribute descriptions; as our experiments in §3.3 show, modifying templates and descriptions can—in some cases—result in quite different self-diagnosis performance. In addition, finding descriptions that are well understood by current generations of language models may be inherently difficult for some forms of bias. We also find that the proposed self-debiasing algorithm is often overly aggressive in filtering out harmless words that do not really contribute to undesired bias in the generated sentence. While this leads to increased perplexity on Wikitext-2 for large values of λ (see Table 2), our human evaluation carried out in §4.1 shows that it does not hurt the fluency or coherence of generated texts. Nevertheless, we believe that developing self-debiasing approaches that perform at least as well with regards to dropping undesired behaviors while maintaining perplexity comparable to regular decoding is an important direction for future work.

We also note that our self-debiasing algorithm is inherently greedy in that decisions for or against a particular word must always be made while only considering its already generated (i.e., left) context. A word that may seem undesirable when only considering its left context may very well be unproblematic once its entire context is taken into account. To some extent, this problem can be alleviated through beam search. Finally, it should also be noted that the decoding time of our proposed algorithm increases linearly in the number of attributes for which self-debiasing is to be performed because a separate self-debiasing input must be processed for each such attribute. This can be problematic in use cases where it is necessary to eliminate a large number of undesired attributes simultaneously.

5.3 Ethical Considerations

Not least because of the limitations discussed in §5.2, our self-debiasing algorithm in its current form is not able to reliably prevent current generations of language models from exhibiting undesired biases or showing toxic behavior—it can merely reduce the probability of this happening for the selected models and on the selected datasets. It should therefore by no means be used as the sole measure to reduce bias or eliminate undesired behavior in real-world applications.

It would be well beyond the scope of this paper to attempt to make decisions on which behaviors and social biases should be avoided by language models. However, we consider it an advantage of our approach that the responsibility for a model's behavior no longer lies exclusively

with its initial developer: Self-debiasing provides an interface to users of a language model that allows them to explicitly set the desired behavior for concrete use cases. For example, there may well be text genres that contain violent language for legitimate purposes (e.g., crime fiction) and in that case, our method allows the user to specify a policy that does not affect violent language, but reduces other undesired attributes. The ability of specifying a policy will be especially beneficial for critical community intermediaries since this feature allows them to explicitly set the undesired attributes.

6 Conclusion

In this paper, we have shown that large language models are capable of performing self-diagnosis, that is, of investigating their own outputs with regards to the presence of undesirable attributes using only their internal knowledge and textual descriptions. Based on this finding, we have proposed a decoding algorithm that reduces the probability of a model generating biased text by comparing the original probability of a token with its probability if undesired behavior is explicitly encouraged.

As our evaluation is limited to two English datasets covering only a small portion of potentially undesired behaviors in an imperfect fashion, it is important to extend our analysis to other kinds of behaviors and biases, languages, benchmarks, and models.

It is clear that self-diagnosis and self-debiasing only reduce and do not eliminate corpus-based bias. For this reason, they are not a viable path towards bias-free models if used in isolation. However, we hope that future work can leverage our proposals, for example, by combining them with complementary models or by extending them to build stronger debiasing solutions.
