ABSTRACT

A model for predicting transition in flows with separation is presented in this study. The two-layer model of turbulence is employed, along with a suitably defined intermittency function, which takes appropriate values in the laminar-, transitional- and turbulent-flow regions. Correlations derived from measurements are used for this purpose. Two test cases were selected: the flow over a long horizontal body with semi-circular leading edge and the flow over the backward-facing step of small height (expansion ratio of 1:1.01). In the former, oncoming flows with a freestream turbulence level encountered in practical applications was considered (0.2% - 5.6%), whereas in the latter the corresponding level was much lower. The Reynolds numbers, based on the diameter in the first case and on the step height in the second, lie in the range of 1600-6600, in which limited numerical investigations were previously available and where bubbles with laminar separation and turbulent reattachment are expected.

The predictions were found to compare well with the corresponding measurements, both in terms of the lengths of the separation and the transition regions and of velocity and turbulence intensity profiles at various streamwise locations. The results show that, for the transition criterion chosen, in all cases transition is completed downstream of the reattachment point and that the rate at which it is completed increases with the freestream turbulence level.

NOMENCLATURE

\[ J = \text{Jacobian of the coordinate transformation matrix, defined as } J = \partial (x, y)/\partial (\xi, \eta) \]
\[ k = \text{Turbulent kinetic energy, non-dimensionalized by } U_1^2 \]
\[ L = \text{Length scale of turbulence (dimensionless)} \]
\[ p = \text{Pressure} \]
\[ P = \text{Dimension scale of turbulence (dimensionless)} \]
\[ Re = \text{Reynolds number based on a characteristic length for each test case (D or H), e.g., } Re = (U_1 D p)/\mu \]
\[ Re_x = \text{Local Reynolds number based on the streamwise coordinate } x \]
\[ Re_y = \text{Local Reynolds number based on momentum thickness } \delta_2 \]
\[ Tu = \text{Freestream turbulence (non-dimensionalized)} \]
\[ \delta = \text{Horizontal cartesian coordinate distance, respectively} \]
\[ \delta_2 = \text{Vertical and horizontal cartesian coordinate distance, respectively} \]
\[ \xi, \eta = \text{Coordinates in the curvilinear (transformed) system} \]
\[ \gamma = \text{Intermittency function} \]
\[ \delta_1 = \text{Boundary Layer Thickness} \]
\[ \delta_2 = \text{Displacement Thickness} \]
\[ \dot{\epsilon} = \text{Rate of dissipation of turbulent kinetic energy, non-dimensionalized by } U_1^2 / D \]
\[ x, y = \text{Dimensionless cartesian coordinate distances, e.g., } X = x/d, \ Y = y/D \]
\[ \mu = \text{Molecular viscosity of air} \]
\[ \mu_t = \text{Turbulent viscosity} \]
\[ \mu^* = \text{Viscosity ratio } \mu^* = \mu_t/\mu \]

and as research in the area of turbulence modelling itself ad-
ing mainly attached flow configurations. Most of them were
transition takes place. In most cases, the separation bubble is lami-
lar and the flow is turbulent at or soon after the reattachment
(1951). Separated-flow transition occurs when a laminar bound-
ary layer, which is a well known problem in fluid mechan-
isics and has been treated by linear stability analysis (Schlichting,
1979). It normally occurs in flows with low freestream turbu-
ence. Bypass transition is due to the entrainment and subse-
quent growth of turbulent spots in the laminar boundary layer
and occurs at high freestream turbulence levels. Its analyti-
tical treatment is based on the turbulent spot theory of Emmons
(1951). Separated-flow transition occurs when a laminar bound-
ary layer separates from a surface and a separation bubble
is formed. Then a free-shear layer develops, along which the tran-
sition takes place. In most cases, the separation bubble is lami-
nar and the flow is turbulent at or soon after the reattachment
point, in which case the flow situation can be described as lami-
nar separation - turbulent reattachment.

A large number of computational studies has been presented
over the past decades on boundary-layer transition, considering
mainly attached flow configurations. Most of them were based on modifications of previously existing turbulence models,
and as research in the area of turbulence modelling itself ad-
vanced, so did transition modelling. An extensive account of the
recent modelling efforts in transition, particularly those made
by European researchers, has been presented by Savill (1985).
This reflects the activities of the Special Interest Group (SIG)
on Transition formed within ERCOFTAC ². The most popular
approach seems to be the low Reynolds k — c model, both in a
parabolic and an elliptic form, but also integral methods, non-
 isotropic k — c models, Reynolds stress models, models including
transport equations for intermittency and large eddy simulation
have been used among others. All these have been used for com-
putations under a variety of external flow conditions, such as
level of freestream turbulence and pressure gradient, the latter
of which can have zero or non-zero values and can be of favorable
or adverse nature.

In the study of separated-flow transition, the most common
configuration has been the leading edge separation bubbles on
airfoils. The various methods that have been adopted for this
purpose have been classified by Walker et al. (1988) as : a)
Semi-empirical methods, b) Viscous-inviscid interaction meth-
ods and c) Navier-Stokes solutions, of which the first two classes
are the most widely encountered in the literature. An example
of semiempirical methods and correlations was offered by the
work of Roberts (1980), which aimed at analysing the phenom-
ena associated with leading-edge separation bubbles on airfoils.
He discussed in detail the features of the two main types of sep-
aration bubbles, namely short and long bubbles. The short ones
have a local effect on the flow and only slightly affect the invis-
ecid flow outside the bubble. Long bubbles on the other hand
exhibit a significant interaction with the external flow, so that
the pressure distribution modified markedly compared to the in-
viscid case. He defined four flow regimes based on very low,
low, medium and high chord Reynolds numbers which give com-
plete separation, long bubbles, short bubbles and no separation
respectively.

Some of the earliest attempts to investigate transition in sep-
aration bubbles were based on analytical methods which distin-
guished between an inviscid region outside the bubble, where
potential-flow theory could be employed, and a viscous region
inside the bubble where boundary-layer analysis could be used.
Thus each region was treated independently and an iterative
procedure was followed, during which an attempt was made to
match the two results at the interface between the two regions.
Among the most representative studies in this area are those by
Crimi and Reeves (1976) and Kwon and Pletcher (1979). Both
were interested in leading-edge separation bubbles on airfoils
and the prediction of the phenomenon of 'bursting', which could lead
to stall at a given angle of attack. A constant-thickness airfoil
with a cylindrical nose was the configuration used by Arena and
Mueller (1980) for low-speed wind tunnel measurements in an at-
tempt to study leading-edge separation bubbles. Different angles
of attack, flap angles and chord Reynolds numbers in the range
150,000-460,000 were investigated. Bellows and Mayle (1986)
performed heat transfer measurements on a similar body, at
Reynolds numbers, based on the diameter, Re = 80,000, 100,000
and 120,000 and freestream turbulence level of 0.4 %.

In this study, some of the ideas used in previous efforts to
model separation bubbles as described above are employed, in
conjunction with a full, elliptic simulation of the flow over a body
with a semi-circular leading edge and a backward facing step of

² European Research Community On Flow Turbulence And Combustion
small height. The two geometries are shown in Fig. 1. These were proposed in the course of the activities of the ERCOFTAC SIG on Transition mentioned earlier (Savill, 1992). The first flow situation has not been very extensively investigated in the past and only the experimental studies of Arena and Muller (1980), Bellows and Mayle (1986) and Malkiel and Mayle (1996) are on similar flows, but the authors considered higher Reynolds numbers and mostly non-zero angles of attack.

The second testcase, the backward-facing step, has been much more frequently investigated. Many test calculations have been carried out for laminar flow ($Re \leq 800$, based on the step height) and fully turbulent flow ($Re \geq 5000$ or higher), but very few attempts have been made to simulate the flow in the transition regime, such as for instance the studies of Kariadaklis et al. (1990) and Kaiktsis et al. (1991). The latter has reported bifurcations to three-dimensional and oscillatory flow patterns at the early stages of transition. The expansion ratios (outlet height/inlet height) associated with the step were in most cases 1.5 or larger. On the other hand, the present value is very close to unity, due to the very small step height, namely 1.012. The step-height Reynolds number is equal to 4095.

Here, both testcases described are simulated numerically in the transitional regime. In both of them laminar separation is expected, with a separation point whose location is either not known in advance (case 1) or is fixed (case 2, step corner). Eventually a fully-turbulent reattached flow is expected. The full elliptic, two-dimensional flow equations are solved, along with a two-layer model of turbulence, where the viscosity is adjusted through an intermittency function in the laminar, transitional and turbulent flow regions. This function is defined in such a manner that previous findings on separated flows can be incorporated into the transition model, thus allowing some elements of the physics of these particular flows to be accounted for. Experimental data for testcase 1 were obtained at the Rolls-Royce Applied Science Laboratory (RRASL), Derby, UK (Coupland, 1995) and for testcase 2 at the Engineering Department of Cambridge University, Cambridge, UK (Savill, 1992).

MATHEMATICAL MODEL

Model Equations

In a two-dimensional, Cartesian coordinate system, the steady equations governing incompressible flow and using the $k - \epsilon$ turbulence model, can be written in the following dimensionless and compact form:

$$\frac{\partial F}{\partial X} + \frac{\partial G}{\partial Y} = \frac{\partial F_d}{\partial X} + \frac{\partial G_d}{\partial Y} + S \quad (1)$$

where $F$ and $G$ are the convective flux vectors, defined as:

$$F = \begin{bmatrix} \frac{\partial \overline{U}}{\partial X} + P & \frac{\partial \overline{V}}{\partial X} \\ \frac{\partial \overline{V}}{\partial Y} \\ \frac{\partial \overline{U}}{\partial X} \end{bmatrix}, \quad G = \begin{bmatrix} \frac{\partial \overline{V}}{\partial Y} \\ \frac{\partial \overline{V}}{\partial X} + P \frac{\partial \overline{V}}{\partial X} \\ \frac{\partial \overline{U}}{\partial X} \end{bmatrix}, \quad (2)$$

$F_d, G_d$ are the diffusive flux vectors and $S$ is a source term.

vector $F_d$ and $S$ are defined as:

$$F_d = \frac{1}{Re} \begin{bmatrix} 0 \\ (1 + \gamma \mu^i_\epsilon) \left( \frac{\partial \overline{U}}{\partial X} \right) \\ (1 + \gamma \mu^i_\epsilon) \left( \frac{\partial \overline{V}}{\partial Y} \right) \end{bmatrix}, \quad S = \begin{bmatrix} 0 \\ 0 \\ S_x \\ S_z \end{bmatrix}, \quad (3)$$

and $G_d$ is defined accordingly, whereas:

$$S_x = \gamma P_x - \epsilon, \quad S_z = C_1 \gamma P_x \left( \frac{\epsilon}{k} \right) - C_2 \left( \frac{\epsilon^2}{k} \right) \quad (4)$$

$$P_x \equiv \frac{1}{Re} \mu^i_\epsilon \left( \frac{\partial \overline{U}}{\partial X} \right)^2 \frac{\partial \overline{U}}{\partial X} + \frac{\partial \overline{U}}{\partial X} \frac{\partial \overline{U}}{\partial X} \quad \mu^i_\epsilon = C_\mu \frac{k^2}{\epsilon} Re \quad (5)$$

The standard values of the $k - \epsilon$ model constants are used: $\sigma_k = 1, \sigma_\epsilon = 1.3, C_1 = 1.44, C_2 = 1.92, C_\mu = 0.09$. $\gamma$ is the intermittency function used to model transition and will be defined below. Since here a two-layer model is employed, the $k - \epsilon$ model is used only in the outer region. In the near-wall region a one-equation model is used as explained below, whereby the $\epsilon$ equation is not solved. For computational domains of non-rectangular shape, such as the one in testcase 1, a curvilinear,
boundary-fitted coordinate system \((\xi, \eta)\) is employed. The chain rule is used for the transformation of the derivatives from the cartesian to the curvilinear system and Eq. 1 can be written as:

\[
\frac{\partial F}{\partial \xi} + \frac{\partial G}{\partial \eta} = \frac{\partial \tilde{F}_d}{\partial \xi} + \frac{\partial \tilde{G}_d}{\partial \eta} + J \bar{S}
\]  

(6)

Boundary Conditions

In both cases an inlet velocity and an inlet freestream turbulence level are specified. At the outflow, placed sufficiently far from the separation bubble, all streamwise gradients are taken as zero. On the solid surfaces the no-slip conditions are applied.

In testcase 1, the computations extend all the way to the opposite wall, where the viscous sublayer is not resolved but wall functions are used. Due to the symmetry of the geometry, only the upper half of the flow is calculated and a symmetry condition is imposed at the symmetry plane upstream of the body. In testcase 2, due to the large distance of the opposite wall in the experiments, the upper boundary is taken midway across the channel height, where symmetry conditions are imposed.

Of utmost importance in transition modelling, are the inlet conditions for the turbulence quantities. For testcase 1, it was specified (Savill, 1992) that the freestream turbulence \(T_u\), under the prevailing zero-pressure-gradient conditions, decays in a power-law fashion, while the dissipation length scale \(L_e\) increases with the square-root of the streamwise distance. Depending on the properties of the turbulence-generating grids used in each subcase, suitable constants of the power-law expression were computed, using measured values of freestream turbulence above the body surface that were provided. Once the expressions for \(T_u\) and \(L_e\) are fully determined, their corresponding inlet values can be determined by upstream extrapolation. The value of dissipation rate at the inlet is in turn obtained from the relationship \(L_e = k^{3/2}/\epsilon\) and the turbulent viscosity at inlet from Eq. 5. In testcase 2, Blasius conditions at the inlet are proposed, along with a measured, given profile for the turbulence intensity, while for the dissipation length scale a profile obtained from the relationship \(L_e = \min\{x, y, 0.085 \delta\}/C_{D}^{1/4}\) was recommended (Savill, 1994), where \(x = 0.41\) (von Karman’s constant) and \(y\) is the distance from the bottom surface of the inlet channel.

Two-layer model

The two-layer model as described in the paper by Rodi (1991) is used in the present computations. It is a combination of the standard \(k-c\) model, used in the outer region, and the Norris-Reynolds one-equation model applied in the near-wall region. Since the computations here are carried out in non-dimensional variables, the various relationships are presented in a dimensionless form. Therefore, in the Norris-Reynolds approach, the turbulent viscosity is given by the following expression:

\[
\mu_t = Re f_{\mu} C'_{\mu} \sqrt{k} L
\]  

(7)

where:

\[
f_{\mu} = 1 - \exp \left( -\frac{Re_k}{A_{\mu}} \right)
\]

\[
Re_k = Re \sqrt{k} Y_n, \quad L = C_D \kappa Y_n
\]  

(8)

and : \(C'_{\mu} = 0.084, A_{\mu} = 50.5, C_D = 6.41, \kappa = 0.41, Y_n\) is the dimensionless distance normal to the wall. Only the \(k\) equation is solved in the near-wall region, with the source term \(S_k\) of Eq. 4 using the following value of \(\epsilon\) :

\[
\epsilon = \frac{k^{3/2}}{L} \left( 1 + \frac{1}{Re \sqrt{k} L} \right), \quad C_r = 13.2
\]  

(9)

The criterion for switching between inner and outer region modelling is determined by the value \(f_s \approx 0.95\) (Rodi, 1991) or the boundary layer edge, whichever is attained first as one moves away from the wall. This model has been previously used to compute transitional, attached flows in turbine cascades (Cho et al., 1993). Transition was effected by an empirical relation for \(Re^*\) from a large value in the laminar flow to \(Re^* = 25\) in fully turbulent flow. The start of transition was determined with the empirical formula of Abu-Ghannam and Shaw (1980). Here, the latter procedure is not used, but \(Re^*\) is kept constant at \(Re^* = 25\) (turbulent flow) and the transition process is controlled instead through the intermittency function \(\gamma\), as shown in Eqs. 3 and 4 and as will be described below.

Transition Model Parameters

The intermittency function \(\gamma\), appearing in Eqs. 3-4 as a multiplication factor for the eddy viscosity, represents the fraction of time during which a flow at the given location is turbulent (Mayle, 1991). The values of \(\gamma\) range from 0, corresponding to laminar flow, to 1, which indicates a fully-turbulent flow. Values between 0 and 1 represent a state of transition from laminar to turbulent flow at a particular point. The rate at which the values of \(\gamma\) increase from 0 to 1 during transition is determined by the rate of the turbulent spot production (Emmons, 1951) and is generally of exponential nature. Different investigators have proposed different parameters that control this exponential growth and presented \(\gamma\) as a one-dimensional function of the streamwise coordinate, corresponding to values near the wall (near-wall intermittency) (Mayle, 1991). Such expressions, accompanied by correlations for the onset of transition and the extent of the transition region may then be used for modelling the flow in the transition region.

Here, the following expression is used for intermittency :

\[
\gamma(z) = 1 - \exp \left[ -G(z - z_\tau) \int_{z_\tau}^{z} dz' \frac{U_{\infty}^3}{U_{\tau}^3} \right]
\]  

(10)

where :

\[
G = \frac{\exp(0.99 T_u)}{100} \frac{U_{\infty}^3}{\nu^2} Re_{2,ir}^{-4/3}
\]  

(11)

proposed by Rodi and Schöning (1987) as an extended version of the work by Chen and Thyson (1971). This expression involves the value of the Reynolds number \(Re_{2,ir}\) based on the momentum thickness at the transition point and the coordinate of the transition point \(z_\tau, Re_{2,ir}\), is obtained at each streamwise location from the following correlation :

\[
Re_{2,ir} = \left( 1 + \frac{0.05}{\exp(0.365 T_u)} \right) Re_{2,ir}^* + \frac{17000}{\exp(0.509 T_u)}
\]  

(12)

The coordinate at the start of transition \(z_{\tau}\) is taken as the location at which the local value of \(Re_{2}\) exceeds the value of \(Re_{2,ir}\) computed from Eq. 12. The above expression has been developed by Rodi and Schöning (1987), by modifying previous published
correlations which incorporated the coordinate of the separation point (see, for instance, Kwon and Pletcher (1979)). These were based on the assumption that transition starts when the maximum displacement thickness due to separation is attained, which coincides with the end of the constant pressure region. Rodi and Schöning (1987) introduced the momentum-thickness Reynolds number instead of the local Re in the correlations, along with the effect of the freestream turbulence. The various coefficients involved were obtained by optimization, based on the experimental data of Gotthardt (1983) and Haas et al. (1987). As can be observed, this correlation involves the Reynolds number at the separation point and therefore it is particularly suited for separated flows. The good prediction of the separation point and the accurate estimation of the various boundary layer thicknesses are essential to the successful use of this model.

COMPUTATIONAL SCHEME

Main Features

The code FAST-2D \(^3\) (Zhu, 1991a) was used for the present computations. This was developed at the Institute for Hydromechanics, at the University of Karlsruhe, Germany over the past decade by various researchers. A detailed description of it, or more strictly its three-dimensional version, is given in the paper by Majumdar et al. (1992). Its main features consist of a control-volume approach, discretization of Eq. 6 in a generalized, non-orthogonal coordinate system, where the cartesian velocity components are used to describe the flow field. The code is based on the pressure-correction algorithm SIMPLE (Patankar, 1980) and its variant SIMPLC (Van Doormal and Raithby, 1984), the latter of which was used in the present computations. A non-staggered grid arrangement and the momentum interpolation procedure of Rhie and Chow (1983) is used to avoid the checkerboard splitting. The convective terms are discretized using the HLPA scheme (Hybrid Linear / Parabolic Approximation) described by Zhu (1991b). This is a higher-order, bounded scheme, with good stability properties.

Computational Domain and Grid

The extent of the computational domains for both cases is shown in Fig. 1. For the first testcase, the horizontal surface of the body is equal to exactly 100 diameters, while vertically the domain is extended up to the wind tunnel wall, as specified by the experimental setup. For the step, the distances chosen (80H downstream of the step, 42.8H vertically) were eventually found to be sufficient to avoid any undesirable boundary influence on the solution, after several possibilities were tested. At the midheight of the test channel a symmetry condition was employed. The grids used in the computations for the two testcases are shown in Fig. 2. After several attempts, the final grid dimensions which were considered necessary for a good resolution of the body surface in case 1 were 142 \( \times \) 102, with 142 points in the streamwise direction. The grid spacings were stretched in the streamwise direction towards the curved surface of the body. In the second testcase, the same number of points was used. Here the emphasis in the stretching of the grid was towards the shear layer expected to develop as the flow separates at the corner.

\(^3\)FLOW Analysis Simulation Tool of 2-D

Fig. 2: Section of the computational grid for the two testcases shown in Fig. 1.

Therefore stretching in both the upward and downward direction was used towards the approximate vertical location of the shear layer. In both cases, the grid dimensions and stretching factors used yielded values of \( Y^+ \) at the first grid point from the wall of the order of 1 or less, therefore ensuring a fair amount of grid points inside the boundary layers.

Procedure and stability considerations

The velocity components and the pressure were initialized with the laminar flow solution obtained on the same configuration for a sufficiently lower Reynolds number. The computations proceeded until the root-mean square residuals of all variables were reduced to the order of \( 10^{-5} \) or less. During the early attempts, it became evident that the numerical procedure tended to become unstable, especially in testcase 2 where the level of freestream turbulence is very low, and multiple separation bubbles developed. It was soon realized that this was due to setting \( \gamma = 0 \) in the laminar-flow regions. It was therefore found necessary to avoid letting the turbulent viscosity go to zero in the diffusion terms of Eq. 3 in these regions. The intermittency was instead set to 1 in the diffusion terms (but not in the production terms) in the laminar region in the free stream. A small amount of diffusion was also allowed in the laminar boundary layer, by setting \( \gamma \) to a small value, in the range 0.1-0.2, again in the diffusion terms only. Such values were found to be adequate for numerical stability without affecting the overall results, after
experimentation in several cases with various flow conditions, and they were maintained in that range in all subsequent calculations. This practice was also directed by physical reasoning, since otherwise the diffusion of freestream turbulence into the laminar boundary layer would not have been properly accounted for and since it was also known from the measurements that the oncoming flow carried some amount of turbulence with it, both in the free stream and within the laminar boundary layer before transition.

RESULTS AND DISCUSSION

Testcase 1

The flow conditions which were specified for the body with the semi-circular leading edge are listed in Table 1. Each subcase is characterized by a letter 'a-f'. Results for all these subcases could not be presented here due to limited space, but the reader is referred to the report by Papanicolaou (1996) for additional results. Here only 1c and 1f are presented in detail.

Results for $U_1 = 5 \text{ m/s, } Re = 3293$.

In Fig. 3 a typical streamline plot is shown. A quite sizable separation bubble is present, whose size varies from case to case, as will be demonstrated below. The bubble in case 1c, for instance, had a length roughly equal to 2.3 diameters. The separation point is located slightly upstream of the beginning of the horizontal surface of the body. On the same figure, the streamwise intermittency distribution $\gamma(X)$ is also shown. The predicted transition point is located at $X_T = 2.41$ diameters from the leading edge. This corresponds to a distance equal to 85% of the bubble length. The transition ends at a streamwise coordinate of $X_T = 2.83$, yielding a total length of transition equal to 0.42 diameters. The predicted transition behavior appears to be more in accord with the findings of Walker (1992), than those of Mayle (1991), as far as the end-of-transition point is concerned. More specifically, here the transition process seems to be completed downstream of the reattachment point, i.e., the flow is not fully-turbulent at reattachment. However, the end-of-transition locations here, obtained for $\gamma = 0.99$, were the outcome of a stricter transition criterion which used the intermittency values computed as a function of the freestream value of $Tu$ (Eq. 11). Since assuming a crossflow variation for the intermittency was outside the scope of this work, using the freestream conditions to represent each streamwise coordinate was the most convenient choice. It is expected that by taking into account a crossflow distribution of intermittency, such as those measured recently by Malkiel and Mayle (1996) or Hazarika and Hirsch (1996), and by using the local peak value of the intermittency to monitor transition instead, an earlier end-of-transition point $X_T$ will be found. Unfortunately, based on the available data, there is no clear experimental evidence regarding the relative position of the end-of-transition and reattachment points.

The various subcases corresponding to an inlet velocity of $5 \text{ m/s}$ can be compared in terms of the values shown in Table 1. The separation point varies only slightly with the freestream turbulence level $Tu$, while the reattachment point and the start of end-of-transition points are shifted further upstream with an increase in $Tu$. In Fig. 4, for case 1c, calculated and measured values of the boundary-layer thickness $\delta$, maximum velocity of the external flow $U_{\text{max}}$ and shape factor are plotted versus the horizontal coordinate $X$. $\delta$ is defined as the wall distance where the velocity is 0.99 of the maximum value. The comparison with the experimental results can be seen to be good, both in terms of $\delta$ and maximum velocity. The plot of $U_{\text{max}}$ indicates that the effect of the bubble extends down to about five body diameters from the leading edge. The shape factor plot exhibits a sharp peak typical of a separation bubble, (somewhat excessive in the calculations) before an asymptotic value of 1.44 is attained. This is very close to the value reported by Schlichting (1979) for turbulent boundary layers on a flat plate. The comparison with the measurements appears fairly good, except for some under-prediction of $U_{\text{max}}$ in the separation region.

In Fig. 5 additional comparisons with measured data are shown, this time for the skin friction coefficient $C_f$ and the Reynolds number $Re_u$ based on the momentum thickness, both plotted against the local Reynolds number $Re_x$. The bubble location in the plot of $C_f$ is indicated by zero values in the measurement data and by negative values in the computations. It can be readily observed that the predicted length and location for the separation bubble agrees quite well with the measurements. The analytical result for the variation of $C_f$ in a turbulent boundary layer over a flat plate, given by a $Re_x^{-0.2}$ relationship (Schlichting, 1979), is also plotted and coincides with the numerical result in the fully turbulent region. The flow behavior in the laminar region is very different from that of a boundary layer over a flat plate, both due to the curvature and the separated region; therefore it would be meaningless to include the analytical result for $C_f$ in the laminar region. Fig. 5 includes a graphical representation of the relationship between $Re_x$ and $Re_u$, as predicted numerically, in comparison with the analytical result for a flat plate. This can be obtained using the corresponding expression for $\delta_3$ (Schlichting, 1979) and indicates a $Re_u^{0.8}$ dependence. In the laminar region the corresponding result is $Re_u^{0.3}$ but, for the same reasons as discussed for $C_f$, the laminar-flow correlation is not shown as not applicable. However, Fig. 5 shows clearly that, as the turbulent regime establishes, the analytical curve is asymptotically approached by the numerical results.

Fig. 6 compares predicted velocity profiles for case 1c with the corresponding measured ones, at several streamwise distances from the leading edge. The region of reversed flow can be observed in the first three profiles and the comparison is generally good, except for some indication of delayed reattachment. For the same streamwise locations, Fig. 7 compares predicted turbulence intensity profiles for case 1c with the corresponding measured values. The comparison is reasonably good for most profiles. In the last profile, an under-prediction of the maximum value of the intensity is observed, which is a known shortcoming of the Norris-Reynolds model and it is due to an overestimation of $\epsilon$ (see Rodi et al., 1993). Equally good results were also obtained for the other three values of freestream turbulence listed on Table 1 and corresponding to $U_1 = 5 \text{ m/s}$. The transition was found to be very abrupt for the highest value of $Tu$ and the length of the bubble the smallest of all cases (roughly 1.5 diameters). For the lowest value of $Tu$, the transition process was slow, but the length of the bubble not significantly affected.
By reducing the inlet velocity to 2.5 m/s (case 1e), and at the same value of Tu as for case 1c, a longer bubble was obtained and a significantly delayed start of transition.

Results for U1 = 10 m/s, Re = 6586. The results that follow are for testcase 1f, which has a similar value of freestream turbulence as in case 1c (2.5 %), but a higher velocity, namely 10 m/s. The corresponding streamline plot for this case is shown in Fig. 8 and shows that the length of the bubble (1.1D) is much smaller than for case 1c. Transition starts therefore much earlier, but the total length of the transition region (approximately 0.7 diameters) is not significantly different from case c, indicating that it is mainly dependent on the freestream turbulence level and not so much on the Reynolds number.

Figs. 9 and 10 show the various boundary layer quantities that were previously presented for case 1c. Again, overall good agreement can be observed. In particular the plot of Cf shows a very good prediction of the reattachment point. The Re2 vs. Re2 plot shows again the attainment of turbulent flow conditions at increasing Re2 when compared with the analytical curve. The velocity profiles and turbulent intensities for this case verified once again the good prediction of the reattachment point and exhibited a good overall agreement. In Fig. 11 the pressure coefficients are plotted along the separation and transition regions for cases 1c and 1f. The features typical of a separation bubble, such as a region of constant pressure followed by a downstream region of pressure recovery (Mayle, 1991), can be identified in both cases. The plots further indicate that the start of transition almost coincides with the end of the constant pressure region, as pointed out by Kwon and Pletcher (1979). The pressure recovery is also shown to be complete at the reattachment point.

To summarize, good comparisons with the measured values were obtained for all six cases shown on Table 1. Some discrepancies were observed only in the prediction of turbulence intensities for the smallest value of the freestream turbulence, Tu00 = 0.17 % (case 1a), and for the smallest value of the inlet velocity, U1 = 2.5 m/s (case 1e). Clearly, some experimentation with alternative values of the parameters involved in Eqs. 11 and 12 would be necessary to produce a more universal model, but this was considered outside the scope of the present work.

Comparisons with experimental correlations

The lengths of separation and transition regions for all six computed cases 1a-1f were subsequently compared against each other in a more systematic way. By using the distances Xs, Xr, and Xτ listed on Table 1 one can calculate and plot three suitably defined Reynolds numbers Reτ, Re2, and ReLτ, often used to characterize transition, vs. the momentum-thickness Reynolds number at the separation point Reτ. For instance, Reτ is computed as:

\[ Re_\tau = \frac{u_\tau (\tau - \tau_s) \rho}{\mu} = Re U_1 (X_\tau - X_s) \]  

and similarly the other two numbers. In this manner, plots similar to those presented by Mayle (1991) are constructed and shown in Fig. 12. The correlations proposed by Mayle (1991) and Walker (1992) are also included in this figure. The values of Reτ, appearing here represent a relatively narrow band compared to the results plotted by Mayle (1991) and therefore a new correlation cannot be derived based on the present data. However, one can see that the computed values of Reτ are in reasonable agreement with the correlation of Mayle for long bubbles. There is however one data point which falls exactly on the correlating line of Mayle (1991) for Reτ, for long bubbles. The short bubble correlation is also plotted and cases (d) and (f), where the bubbles are indeed short, are the closest to it. Both correlations have a Reτ dependence, but are multiplied by a different factor. In Fig. 12c, the values of ReLτ are plotted against two different correlations, one proposed by Mayle (1991), valid for both short and long bubbles and suggesting a ReLτ dependence and another one by Walker (1992) where the dependence is ReLτ. Interestingly enough, although qualitatively this study agrees more with the findings of Walker (1992) as far as the end-of-transition is concerned, the present results seem to agree quantitatively better with the correlation of Mayle (1991) for ReLτ, except for one data point, corresponding to the highest freestream turbulence level (5.5 %). Although the correlations of Mayle (1991) where derived from experimental data corresponding to low freestream turbulence levels (0.2-0.5 %), here a good agreement is observed in the range 0.63-2.5 % (cases b,c,e and f).

Testcase 2

Although experimental data were available in this case for three different Reynolds numbers (based on the inlet velocity), Re = 1830, 2535 and 4095 (Savill, 1994), with essentially the same freestream turbulence level Tu of the order 10^-2 %, only the case with the highest Reynolds number (Re = 4095) could be calculated because of numerical instabilities encountered at this low Tu. In Fig. 13 the streamline plot for this case is shown, along with the corresponding streamwise distribution of the intermittency function. The computed flowfield is characterized...

by a relatively long separation bubble (9.54 step heights) immediately downstream of the step, with a small secondary eddy at the foot of the step. The transition process appears to be relatively slow, a fact that was to be expected considering the very low freestream turbulence level of the oncoming flow. Transition starts at about 4.8 step heights downstream of the step and is completed at a distance of about 18.4 step heights.

The experimental data available for this testcase were in terms of streamwise varying values of the momentum thickness, the maximum velocity of the external flow and the shape factor. In Fig. 14 these quantities are compared with the predicted values along the streamwise distance \( x/H \). The agreement is very good for all three quantities and the extent of the separated region is well predicted. Fig. 15 shows the variation of the skin friction coefficient and Reynolds number based on the momentum thickness. No experimental data were provided for these two quantities and the results are only compared with the analytical flat-plate boundary layer correlations. What can be observed is that the reattached shear layer in this testcase deviates somewhat from the results for turbulent flow over a flat plate.

In Fig. 16 velocity profiles are compared at several streamwise locations downstream of the step with the experimental ones. The experimental data in the first two profiles (separation region) are given as zero or constant, positive values, i.e., no negative velocities were measured. Generally the agreement is good, except for some indication of early reattachment in the numerical results. In Fig. 17 the corresponding turbulence intensities, both numerical and experimental are shown, at the same streamwise locations as the velocities. It can be observed that there is some overprediction of the intensity values at the first station but gradually the numerical values approach the experimental ones. The transition process appears to be very rapid at its early stages in the numerical predictions.

CONCLUSIONS

A computational approach based on a two-layer turbulence model and an empirical intermittency function was presented for calculating transition in separated flows. Two testcases were investigated, one involving flow separation due to curvature and the other one due to sudden expansion (step). The transition process was modelled by means of an intermittency function defined through empirical correlations, based on experimental data. These allowed for the effect of separation to be included in the modelling. The results appear promising as for a relatively wide range of external flow conditions (freestream velocity, level of turbulence) corresponding to values of practical interest in turbomachinery flows, generally good agreement with experimental data was obtained. This can be said both for global quantities such as separation length and location of transition, as well as for local velocity and turbulent intensity profiles.

The model behaved better for freestream turbulence levels in the range 0.6 % - 5.6 %, but has been tested also for levels one order of magnitude lower, where it still produced reasonably good results. This study has proven that the intermittency function can be used in several ways in transition modelling, such as for instance in combination with the two-layer model used here, and can lead to successful predictions, but it is necessary to handle with care the laminar-flow regions where this function vanishes, to obtain numerically stable computations.

Available correlations for separated flows based on experimental data such as the ones used here can provide valuable inputs to transitional modelling. However, further experimentation with the various parameters involved in such correlations is needed in order to improve the universality of the models. It is also necessary to investigate additional effects such as rotation or buoyancy and to compute more realistic blade configurations.
