ABSTRACT

In the Netherlands, approximately 60% of drinking water is obtained from (generally anaerobic) groundwater. This requires aeration followed by rapid sand filtration (RSF) to remove iron, manganese, arsenic and ammonium. The mechanisms responsible for their removal or the clogging of RSFs and breakthrough of colloidal iron or manganese oxides have not been fully elucidated in previous studies. In this work, factors affecting iron precipitation have been studied in aerated, continuously stirred bench scale jar experiments to simulate the supernatant layer of submerged sand filters. Time series data of filtered iron concentration and precipitate size have been collected in experiments with synthetic groundwater with and without P, Si, HCO₃ and Ca at neutral pH. We observed that precipitate growth is not influenced by different HCO₃ concentrations but is reduced drastically when natural organic matter (NOM) is present in water and, to lesser extent, Si as well. The addition of P appears to hamper precipitate growth to some extent, but requires more research to fully understand the implications. We also observed that addition of Ca improved the growth of Fe precipitates in the presence of Si and especially NOM. These results have great significance for improving Fe removal efficiency of groundwater treatment plants in The Netherlands and abroad.

Key words: groundwater treatment, iron oxidation, precipitation, rapid sand filtration

HIGHLIGHTS

- Different HCO₃ concentrations have no significant impact on the precipitation of Fe for typical groundwater conditions.
- Silicate additions in the presence of HCO₃ result in reduced Fe precipitation.
- Addition of NOM in the presence of HCO₃, hamper the precipitation growth of Fe.
- The impact of Ca on precipitate growth is stronger for dissolved organic carbon-containing water compared to Si-containing water for typical concentration ranges.

INTRODUCTION

In The Netherlands, 60% of drinking water is obtained by treating groundwater, mostly by aeration and rapid sand filtration to remove impurities such as iron (Fe), manganese (Mn), arsenic (As) and ammonium (NH₄⁺). Drinking water in The Netherlands is generally of high quality, however in some cases discolouration events due to incomplete removal of Fe from groundwater have been reported. Therefore, this study is focused on improving the efficiency of groundwater treatment for effective Fe removal.

When anaerobic groundwater is aerated at water treatment plants e.g. by cascades, oxygen (O₂) diffuses into groundwater and facilitates oxidation of dissolved Fe(II) to insoluble Fe(III)(oxyhydr)oxide precipitates. The Fe(III)(oxyhydr)oxide precipitates are typically removed in submerged rapid sand filters (Beek *et al.* 2016; Vries *et al.* 2016). The ionic composition of groundwater has a major impact on the structure, crystallinity and aggregation behaviour of these Fe(III) precipitates. Previous studies have shown that at near-neutral pH, Fe(II) oxidation by O₂ leads to the formation of moderately crystalline Fe(III) precipitates, such as lepidocrocite, whereby the presence of oxyanions such as silicate (Si), phosphate (P) and arsenate ((As(V)) in water leads to the formation of poorly ordered Fe(III) phases (Voegelin *et al.* 2010; van Genuchten *et al.* 2014a;

Senn *et al.* 2015). The presence of oxyanions during Fe(III) precipitation not only affect the local coordination and ordering in the Fe(III) precipitates, but also decrease the extent of particle aggregation due to a highly negative surface charge which causes repulsion between the particles. This may result in stable colloidal suspensions, especially in solutions devoid of Ca and Mg cations, which are difficult to clarify by sedimentation and/or filtration. Bivalent cations such as Ca and Mg can counteract this repulsion effect of negative particle surface charge and can enhance particle aggregation (Senn *et al.* 2015, 2019; Ahmad *et al.* 2020b). Calcium is also known as a dominant coagulating agent for solutions containing natural organic matter (NOM) and other ions (Sholkovitz & Copland 1981) and is expected to compete with trace metals for binding with NOM (Tipping 1993; van den Hoop *et al.* 1995).

In The Netherlands, the ionic composition of groundwater significantly varies from one groundwater source to another. The impact of variations in key groundwater solutes, including bicarbonate (HCO_3^-), Si, P, NOM and Ca on Fe(III) precipitation and removal at groundwater treatment plants is not yet fully understood. Most groundwater treatment systems are still designed on rules of thumb without detailed understanding of physicochemical processes (Ahmad *et al.* 2018, 2020a). Although the oxidation and precipitation and subsequent aggregation and coagulation of Fe (see e.g. Sholkovitz & Copland 1981; Jarvis *et al.* 2006; Bratby 2016) has been studied before, the rate of precipitation in relation to variations in the composition of groundwater has not received much attention. The residence time in groundwater treatment installations and the half-life of Fe(II) oxidation are comparable (Stumm & Morgan 1996; Vries *et al.* 2016). Hence, we believe that the investigation of the kinetics of Fe(III) precipitation due to Fe(II) oxidation are critical for improving the efficiency of rapid sand filters. To this aim, we qualitatively investigated the influence of HCO_3^- , NOM, Si, Ca and P on the rate of precipitation of Fe when oxidizing Fe(II) in simulated groundwater matrices. The ionic composition of these matrices, i.e. HCO_3^- , NOM, Si, Ca and P concentration, is derived from averaging the groundwater quality in The Netherlands. The scope of this work encompasses the influence of typical (oxy)anions and cations on iron precipitation within a bicarbonate buffered solution. To investigate the precipitation kinetics in the supernatant layer of a submerged sand filter, we used a laboratory simulated environment through the use of an aerated, continuously stirred bench scale jar experiments. It is expected that, in line with previous publications (Jobin & Ghosh 1972a), alkalinity should not impact Fe(II) oxidation at neutral pH, while Ca should have a positive effect on the Fe precipitation rate and Si, P and NOM should have a negative effect (Tipping 1993; van den Hoop *et al.* 1995).

MATERIALS AND METHODS

Initial solutions

Iron oxidation and precipitation rate experiments were performed with different initial solutions (Table 1), produced by dosing chemical stocks in ultrapure water (Milli-Q, produced by purifying distilled water with a Purelab Chorus provided by Veolia). All the initial solutions contained 80.5 μM Fe(II), 8.2 μM Mn(II), 0.60 μM As(III) and 460 μM NaCl, but differed in the concentration of HCO_3^- (1,500–300 μM), Si (320–640 μM), P (15 μM), dissolved organic carbon (DOC) (150–300 μM) and Ca (450–1,800 μM) (see Table 1). These differences in ionic composition were chosen to simulate groundwater quality in The Netherlands. For preparing the stock solutions, reagent grade chemicals were used. Stock solutions of 22.4 g/L FeSO_4 , 61.9 g/L NaHCO_3 , 13.5 g/L NaCl and 1.0 g/L Na_2SiO_3 were prepared by dissolving $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ (CAS: 10025-77-1, 97% purity, J.T Baker, The Netherlands), NaHCO_3 (CAS: 144-55-8, >99% purity, J.T Baker, The Netherlands), NaCl (CAS: 7647-14-5, 99% purity, J. T Baker, The Netherlands) and $\text{Na}_2\text{SiO}_3 \cdot 5\text{H}_2\text{O}$ (CAS: 10213-79-3, 99% purity, Sigma-Aldrich) respectively in ultrapure water. The stock solutions of 49.8 g/L CaCl_2 and 1.0 g/L NaH_2PO_4 were prepared by dissolving CaCl_2 anhydrous (CAS: 10043-52-4, 96% purity, J. T Baker) and $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ (CAS: 10049-21-5, >98% purity, J.T Baker) respectively in 0.1 M HCl. The NOM stock solution of 2.4 g/L DOC was prepared by diluting a primary stock (HumVi, Vitens, The Netherlands, 117.4 g/L DOC) that contained approximately 75% humic substances (HS) (Ahmad *et al.* 2020b), see the composition in Table S1, supplementary material. Arsenic was dosed using a stock solution of 1.0 g/L As_2O_3 (CAS: 1327-53-3, 99% purity, Inorganic Ventures). For pH adjustment, 0.1 M HCl or 0.1 M NaOH is used.

Iron oxidation and precipitation experiments

Iron oxidation and precipitation rate experiments were performed with a 5 liter glass vessel connected to a controller (ez-Control, Applikon® Biotechnology) for adjusting, maintaining and logging (BioXpertV2 software) the pH, temperature, air supply and stirring speed (Figure 1). The experiments were carried out at pH 7.0 and 20 °C, with stirring set to 300 rpm for the first 5 minutes and 80 rpm for the rest of the experiment. The experimental procedure included: (i) preparation of

Table 1 | Composition of the initial solutions used in the precipitation experiments

Impact of ion(s)	Experimental code	Concentration ($\mu\text{mol/L}$)				
		HCO ₃	Si	P	DOC	Ca
HCO ₃	1500HCO ₃	1,475

	2200HCO ₃ + 300DOC + 900Ca	2,213			300	898

In all the initial solutions the concentration of Fe(II), Mn(II) and As(III) was 81, 8.2 and 0.6 μM . All the initial solutions also contained 460 μM NaCl.

the initial solutions in the oxygen-depleted reaction vessel and collection of solution samples for control, (ii) O₂ dosing to allow precipitation of Fe(III) while the suspension was stirred and (iii) collection of suspension samples after 30 minutes, which were filtered over 0.20- μm filters (SpartanTM 30/0.20 RC 0.20- μm syringe filters (GE Healthcare, Buckinghamshire, UK)) to determine the removal of Fe(III) precipitates and co-precipitated species. The removal of Fe was determined from the difference between the measured values of the initial solution and final filtered solution.

Fe, Mn, As, Ca, Si, P were measured using inductively coupled plasma mass spectrometry (ICP-MS) (XSERIES 2, Thermo Fisher Scientific, The Netherlands) using the collected samples before supplying air to the vessel ($t = 0$ minutes) and after 30 minutes. Samples for analysis by ICP-MS were preserved immediately after collection by dosing 50 μL 65% HNO₃ per 50 mL sample and stored at 4 °C. The analysis of DOC in water samples was carried out with a TOC-V_{CPH} total organic carbon analyser (Shimadzu Benelux, 's-Hertogenbosch, The Netherlands). The samples for DOC analysis were conserved immediately after collection by adding 200 μL 30% HCl solution to 100 mL of sample which was closed off airtight and stored at 4 °C. Bicarbonate was analysed by a colorimetric method (HI-3811, Hanna Instruments) using HI 775-26 fresh water alkalinity reagent.

Particle characterization

The size and volume fraction of the precipitates were determined during the experiments by multiple light scattering (MLS) using the Mastersizer 2000 (Malvern Instruments, UK). The MLS device was connected to the reaction vessel (Figure 1) and the suspension was continuously drawn through the Mastersizer measurement cell at a constant flow of 216 mL/minute using a Masterflex easy-load II peristaltic pump combination (Metrohm Nederland B.V. The Netherlands). Malvern instruments Mastersizer 2000 software v5.61 recorded the particle size distribution every 20 s, for the complete duration of the experiment (30 minutes). A scattering coefficient¹ of 2.9 was used to determine the particle size of Fe(III)(oxyhydr)oxide particles (Gregory 2009). From the light scattering data, relative precipitate volume and the size distribution have been determined. The relative precipitate volume is the ratio of the volume of the precipitate with respect to the total volume of the

¹ The scattering coefficient is a measure of the ability of particles to scatter photons out of a directed beam of light. This can be related to the particle's size.

Figure 1 | A schematic overview of the experimental set-up.

measurement cell. It is assumed that detected particles do not represent Fe(III)(oxyhydr)oxide particles if the diameter of 50% of the particles (i.e. d_{50}) is larger than $300\ \mu\text{m}$. This threshold is selected based on the observation that the diameter of 90% of the particles (i.e. d_{90}) never exceeds $300\ \mu\text{m}$. The relative precipitate volume and d_{50} are omitted from the results at the times this particle size threshold is exceeded.

RESULTS AND DISCUSSION

Impact of bicarbonate

The percentage of residual Fe after filtration through a $0.20\text{-}\mu\text{m}$ filter and the relative precipitate volume as a function of different HCO_3^- concentrations are shown in Figure 2(a) and 2(b) respectively. Figure 2(a) shows that residual Fe quickly depletes

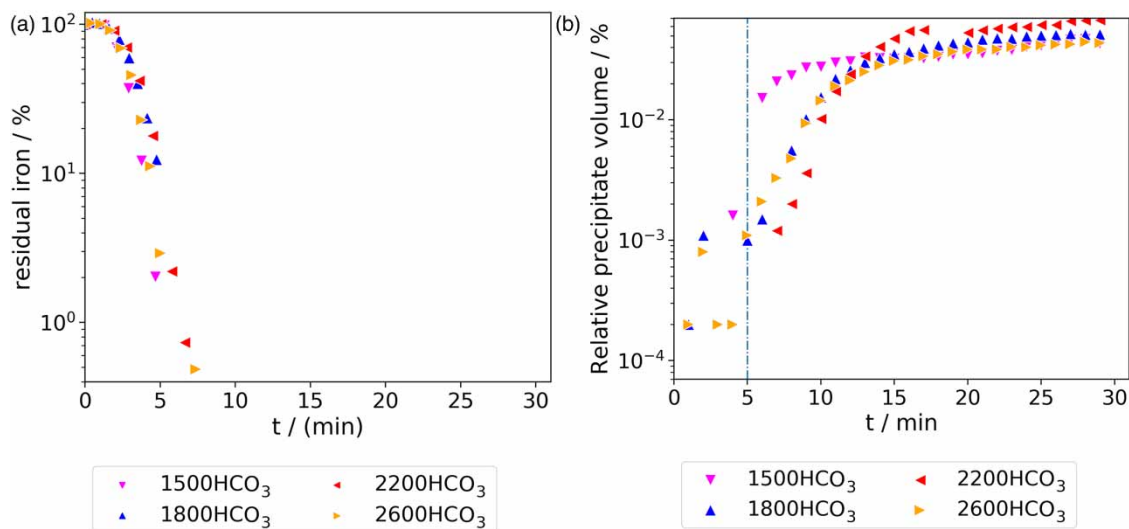

Figure 2 | (a) Residual iron (%) after filtration through a $0.2\text{-}\mu\text{m}$ filter and (b) precipitate volume relative to the total measured volume, as a function of different HCO_3^- concentrations.

by oxidation and reaches to complete absence for all the HCO_3^- concentrations in approximately 7 minutes. The relative precipitate volume appears to stabilize in approximately 15 minutes for all the HCO_3^- concentrations, except that of $1,500 \mu\text{M}$ HCO_3^- which is the lowest HCO_3^- concentration. At this concentration the relative precipitate volume stabilizes already in 7 minutes. The particle size shows the same trend as the relative precipitate volume, i.e. the d_{50} reached approximately $100 \mu\text{m}$ after 30 minutes (Figure S1-A, supplementary material). These results are in agreement with the findings of Jobin & Ghosh (1972b) who showed that Fe(II) oxidation is only hampered when the buffer intensity is sufficiently large (i.e. in the order of $4 \cdot 10^{-3} \text{ eq CaCO}_3/\text{pH}$, hence an alkalinity of more than 16 mmol/L as HCO_3^- at neutral pH, which is substantially higher than the highest HCO_3^- concentration of $2,600 \mu\text{mol/L}$ used in this study. These results show that different HCO_3^- concentrations have no significant impact on the precipitation of Fe and precipitation is completed quite rapidly when the typical residence times of 15–30 minutes for groundwater treatment plants are considered.

Impact of oxyanions and natural organic matter

The percentage of residual Fe after filtration through $0.20\text{-}\mu\text{m}$ filters and the relative precipitate volume as a function of different Si, P and NOM concentrations in the presence of $2,200 \mu\text{M}$ HCO_3^- are shown in Figure 3(a) and 3(b) respectively. Figure 3(a) shows that the percentage of residual Fe concentration stays approximately 100% for most samples, i.e. no significant Fe removal was observed except for the 30 minute sample of $15 \mu\text{M}$ P addition. In all cases, the relative precipitation volume (Figure 3(b)) signal was also unstable, indicating a poor Fe precipitation. The poor Fe precipitation and reduced size of Fe particles due to Si additions are in agreement with previous studies (Liu *et al.* 2007; Piispanen & Sallanko 2011; Kinsela *et al.* 2016; Li *et al.* 2019). Silicate ions bind strongly to Fe(III) precipitate surfaces during Fe(III) polymerization, which modifies two key properties of the suspension. Firstly, by binding strongly to crystal growth sites on the Fe(III) precipitate surface, oxyanions inhibit the formation of crystalline Fe(III) minerals (i.e. lepidocrocite), leading to the formation of poorly ordered Fe(III) precipitates with a large specific surface area (Voegelin *et al.* 2010; van Genuchten *et al.* 2014b). Secondly, sorption of Si leads to negatively charged Fe(III) precipitate surfaces (Kanematsu *et al.* 2013). Therefore, the sorption of Si leads to particles having a highly negative surface charge that makes them less likely to aggregate. Indeed, small amounts of Si are removed (Supplementary Table S2). The work of Piispanen *et al.* shows empirically that if the molar Si/Fe ratio exceeds 2.5, extremely small sized Fe particles are formed. In our study, the molar ratio of Si/Fe in the initial solution was in the range of 4–8, thus much higher. The particle size at $t = 30$ minutes is $7\text{--}10 \mu\text{m}$ after 30 minutes, hence an order of magnitude smaller than the case without Si (Figure S1B, supplementary material).

Our observations related to NOM additions are in agreement with several previous studies which also reported a similar reduction in the removal of Fe(III) in the presence NOM (Vilg -Ritter *et al.* 1999; Davis & Edwards 2017; Ahmad *et al.* 2019). The suppression of Fe(III) removal by filtration has been attributed to formation of soluble Fe(III)–NOM complexes, as well

Figure 3 | (a) Residual iron (%) after filtration through a $0.2\text{-}\mu\text{m}$ filter and (b) precipitate volume relative to the total measured volume, as a function of different Si, P and NOM concentrations in the presence of $2,200 \mu\text{M}$ HCO_3^- .

as formation of Fe(III)–NOM and Fe(III)(oxyhydr)oxide–NOM colloids. However, the characterization of the particles (Fe(III)–NOM or Fe(III)(oxyhydr)oxide–NOM colloids) was not investigated in our study, hence properties of the soluble fractions of Fe(III)–NOM complexes remain unclear. Also, it is known that the presence of Ca^{2+} (or Mg^{2+}) suppresses electrostatic repulsion forces between humic acid–Fe colloids and hence accelerate aggregation (Liao *et al.* 2017) and part of this effect can be seen when comparing Figure 3 with Figure 4. Table S1 shows the characterization of NOM. Note that the influence of different NOM compositions can have a different impact on precipitation (Sharp *et al.* 2006), these impacts were not studied in this work.

Regarding the behaviour of P in our study, sequential precipitation of different Fe(III) phases could be responsible for the initial stability and later destabilization of the suspension at 30 minutes to result in a lower residual Fe concentration after 0.20- μm filtration. In previous studies of Fe(II) oxidation in the presence of P, precipitation of Lp-like material has been observed due to the sequential uptake of P during precipitate formation (Voegelin *et al.* 2010, 2013; van Genuchten *et al.* 2014a, 2014b; Senn *et al.* 2015, 2018). With the initial P/Fe(II) molar ratio of 0.55 (critical ratio) or higher, only P is removed from the solution and Fe(II) oxidation will lead to exclusive formation of amorphous Fe(III) phosphate. However, with an initial P/Fe < critical P/Fe as is the case in our study where P/Fe is 0.2, multiple phases can be formed. These phases include the precipitation of polymeric Fe(III) phosphate, and after the depletion of P from the solution, the formation of more crystalline iron oxide phases (Senn *et al.* 2018). The identity of the iron oxide formed after P depletion strongly depends on oxyanions in water. In oxyanion-free electrolytes, such as in our study, formation of lepidocrocite is likely and could have caused particle growth in the 30 minute sample. Nevertheless, we conclude that more investigations are required to understand the P-related observations from our study.

Impact of calcium

The % of residual Fe after filtration through 0.20- μm filters and relative precipitate volume as a function of different HCO_3^- , Si, P NOM concentrations in the presence of Ca are shown in Figure 4(a) and 4(b) respectively. The results in Figure 4(a) show that, at constant Ca concentration of 900 μM , the efficiency of Fe removal decreases with increasing HCO_3^- concentration. Without calcium, the removal was complete within 10 minutes for the HCO_3^- additions (Figure 2(a)), but with the addition of 900 μM Ca the time to complete removal of Fe by 0.20 μm increases up to 30 minutes. These results needs further investigations to unravel the mechanisms responsible for this peculiar impact of Ca on Fe precipitation in the presence of HCO_3^- .

The addition of 450–1,800 μM Ca in $\text{HCO}_3^- + \text{Si}$ solutions appears to slightly lower the residual Fe concentration (compare Figures 3(a) and 4(a)), potentially attributed to charge neutralization and subsequent precipitate aggregation effect that the Ca ions create for the Si containing disordered Fe(III)(oxyhydr)oxides (Voegelin *et al.* 2010). Particles do hardly grow in size however, reaching to approximately 1–2 μm after 30 minutes (Figure S1C, supplementary material). The addition of Ca in the presence of 150–300 μM DOC significantly improves the removal of Fe by 0.2- μm filters, indicating effective growth and aggregation of the Fe(III), see Figure 4 and Figure S1C (supplementary material) for the relative precipitate volume and d_{50} respectively. These results are in agreement with previous studies (Sholkovitz & Copland 1981; Knocke *et al.*

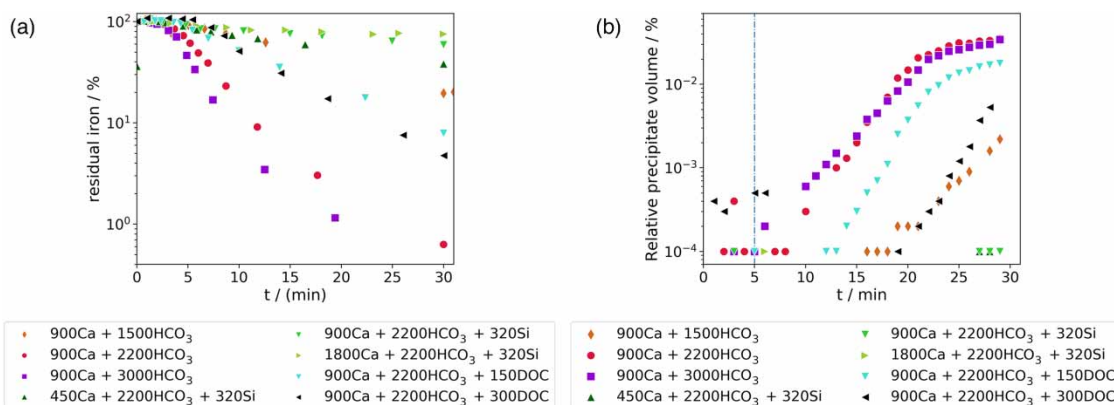

Figure 4 | (a) Residual iron (%) after passing through a 0.2- μm filter and (b) precipitate volume relative to the total measured volume, both shown as time series. See Table 1: for explanation of the labels.

1994). This can be explained based on the influence of DOC and Ca on the surface charge of the Fe precipitates. Because the NOM used in this study is largely composed of negatively charged HS, its complexation with Fe precipitates will increase the negative charge of the surface, thus hampering precipitate growth. However, when Ca is present in the solution, it can bind with these DOC–Fe complexes and reduce the surface charge to promote precipitate growth as was also seen in e.g. the work of Liao *et al.* (2017). Note that Si and DOC are filtered out, together with Fe (supplementary material Table S2). Moreover, no calcium was removed by this filtering.

The implications of this study for groundwater treatment practice could be manifold. First, an expected increase in rainfall due to climate change, can cause the mobilization of NOM in drinking water sources, leading to increased levels of dissolved organic matter (DOM) and HS, alterations to their structure and reactivity (Lipczynska-Kochany 2018). Lipczynska-Kochany also anticipated increased desorption from soil and sediments, as well as re-mobilization of metals and organic pollutants. In addition, the increased levels of acidic atmospheric CO₂ participates increasingly in the weathering of carbonate and silicate minerals, leading to more bicarbonate, Ca⁺² and other cations in drinking water sources (Qafoku 2015). While a change in only bicarbonate does not alter (Fe) precipitation dynamics, changes in calcium concentration does. This could be exploited by water utility operators for further optimization of the iron removal efficiency. Moreover, precipitation dynamics are tightly linked with oxidation dynamics. As a result of the pre-aeration step in rapid sand filtration treatment, anaerobic groundwater containing Fe(II) oxidizes via Fe(III) into Fe(hydr)oxides even in the absence of suspended particles or any other complexation agents by homogeneous chemical kinetics, also known as homogeneous oxidation (Davison & Seed 1983; Moses & Herman 1989). An auto-catalytic process, so-called heterogeneous oxidation, occurs if suspended precipitates allow for sorption and surface complexation with ferrous iron ions (Sung & Morgan 1980; Stumm & Sulzberger 1992; Sharma 2001). Heterogeneous oxidation is a dominant process in the removal of Fe by RSFs (Wolthoorn *et al.* 2004; Vries *et al.* 2016), but becomes retarded when P, Si or HS are present (Wolthoorn *et al.* 2004). Hence, (also) ionic strength and oxyanions can affect the rate of heterogeneous oxidation as well as the charge of Fe(III) (hydroxy)oxide precipitates, and leads to altered precipitation and coagulation characteristics.

Concluding, depending on aquifer characteristics and mineral weathering, the current operation of groundwater treatment sites might be in need of evaluation and further investigation whether additional measures are needed to keep Fe and other metal ion levels in drinking water at an acceptable level. For instance, in groundwater coming from calcareous soils, elevated levels of Ca and HCO₃ enhance precipitation of Fe and coagulation of HS (Ahmad *et al.* 2020c). Possible softening of the treated groundwater could therefore lead to a more effective overall treatment when placed after RSF and carry-over filtering and also allow reuse of calcite granules when calcite pellet contactors are used (Schetters *et al.* 2014; Tang *et al.* 2019). For optimization of drinking water production and water source management under changing conditions, it is necessary to investigate the mechanisms that underpin the interplay of precipitation, colloidal stability and oxidation to arrive at an evidence-based plant operation. This requires, amongst others, that the relation between precipitation rate and water composition as shown in this paper, needs to be quantified to eventually capture that in a model.

CONCLUSIONS AND IMPLICATIONS

We studied the precipitation of Fe in simulated groundwater solutions with different concentrations of HCO₃, Si, P, NOM and Ca, reflecting typical groundwater quality conditions in The Netherlands. We conclude that the different HCO₃ concentrations have no significant impact on the precipitation of Fe and precipitation is completed in the typical residence time of groundwater treatment plants. Silicate additions in the presence of HCO₃ result in reduced Fe precipitation, probably because of the negatively charged silicate–iron co-precipitate surfaces because this hampers precipitate growth. The additions of NOM in the presence of HCO₃, drastically hamper the precipitation growth of Fe, potentially due to the formation of soluble Fe(III)–NOM complexes. Phosphate- and bicarbonate-containing solutions initially hamper precipitate growth but more work is needed to conclude something definitive on the impact of P on Fe precipitation dynamics. Addition of Ca improves Fe precipitate growth in the presence of Si and NOM, potentially attributed to the charge neutralization impact of Ca.

These results clearly indicate that, when designing RSF for iron removal, attention should be paid to the whole water matrix. Moreover, mineral weathering is accelerated by climate change and causes rising Ca and DOC levels in current drinking water sources. Consequently, monitoring of water compositional changes and iron removal is needed to assess whether operational measures in RSF groundwater treatment should be taken.

ACKNOWLEDGEMENTS

This research is financed by the Joint Research Programme of the Dutch Water Companies (BTO). Discussions with and feedback from the members of the project steering committee, i.e. Stephan van de Wetering, Simon Dost, Frank Schoonenberg, Ben Cools, and Alexander Rohling, have contributed to this work and are highly appreciated. We would like to thank Professor Emile Cornelissen (KWR, UGent) and the anonymous reviewers for their critical review of the paper.
