

Antiangiogenic Role of Somatostatin Receptor 2 in a Model of Hypoxia-Induced Neovascularization in the Retina: Results from Transgenic Mice

Massimo Dal Monte,¹ Maurizio Cammalleri,¹ Davide Martini,^{1,2} Giovanni Casini,² and Paola Bagnoli¹

PURPOSE. To determine whether the somatostatin receptor 2 (*sst*₂) influences angiogenesis and its associated factors in a model of hypoxia-induced retinal neovascularization.

METHODS. *sst*₁-knockout (KO) mice, in which *sst*₂ is overexpressed and overfunctional, and *sst*₂-KO mice were used. Angiogenesis was evaluated in fluorescein-perfused retinas. Angiogenesis-associated factors were determined by RT-PCR and immunohistochemistry.

RESULTS. Retinal neovascularization was increased in *sst*₂-KO mice, but remained unchanged in *sst*₁-KO compared with wild-type (WT) mice. Retinal levels of *sst*₂ mRNA were not affected by hypoxia. Normoxic levels of angiogenesis regulators were similar in WT and KO retinas except for mRNA levels of IGF-1, Ang-2, and its receptor Tie-2. In WT, hypoxia induced an increase in mRNA levels of (1) VEGF and its receptors, (2) IGF-1R, and (3) Ang-2 and Tie-2. The increase in VEGF and IGF-1R mRNAs was more pronounced after *sst*₂ loss, but was less pronounced when *sst*₂ was overexpressed. In addition, in hypoxic retinas, *sst*₂ loss increased IGF-1 mRNA, whereas it decreased Ang-1, Tie-1, and Tie-2 mRNA levels. Moreover, Tie-1 mRNA increased when *sst*₂ was overexpressed. Immunohistochemistry confirmed the results in hypoxic retinas on increased expression of VEGF, IGF-1, and their receptors after *sst*₂ loss. It also allowed the localization of these factors to specific retinal cells. In this respect, VEGFR-2, IGF-1, and IGF-1R were localized to Müller cells.

CONCLUSIONS. These results suggest that *sst*₂ may be protective against angiogenesis. The immediate clinical importance lies in the establishment of a potential pharmacological target based on *sst*₂ pharmacology. (*Invest Ophthalmol Vis Sci.* 2007;48:3480–3489) DOI:10.1167/iovs.06-1469

The abnormal formation of new blood vessels characterizes a variety of retinal diseases, including diabetic retinopathy,¹ and requires the involvement of vascular endothelial growth factor (VEGF), insulin-like growth factor (IGF)-1, and their receptors VEGFR-1, VEGFR-2, and IGF-1R. Although the

available information on their expression in the retina is far from being exhaustive, these factors have been localized to both retinal cells and microvascular endothelium.^{2–6} Retinal neoangiogenesis is always associated with an increase of VEGF and its receptors^{2,3,7} but not of IGF-1.^{8–10} Of the other downstream factors affecting blood vessel growth, recent results indicate that Ang-1 and -2 and their tyrosine kinase receptor Tie-2 are regulated by hypoxia and play a role in retinal neovascularization.^{11,12} Although a ligand for Tie-1 has not been found, it has recently been demonstrated that Ang-1 can induce Tie-1 phosphorylation.¹³

The potential antiangiogenic role of the peptide somatostatin-14 (SRIF) and its analogues has received much attention,¹⁴ and it involves partial correction of systemic growth hormone dysregulation or inhibition of angiogenesis-associated factors.^{15–17} Of the five SRIF receptors mediating SRIF actions, *sst*₂ is a likely candidate to mediate the angioinhibitory activity of SRIF. Indeed, analogues with high affinity for *sst*₂, such as octreotide and BIM23027, counteract the growth factor-induced proliferation of bovine retinal endothelial cells under hypoxia.¹⁸ They are powerful inhibitors of neovascularization in models of proliferative retinopathies.^{15,19} In addition, octreotide inhibits the IGF-1-mediated induction of VEGF in human retinal pigment epithelial (RPE) cells.¹⁶ Moreover, octreotide retards retinopathy progression in diabetic patients in whom photocoagulation has failed.²⁰ However, despite the growing use of *sst*₂ agonists as antiangiogenic agents, the mechanisms by which these peptides inhibit the growth of new vessels has not been fully delineated.

Both *sst*₁- and *sst*₂-knockout (KO) mice have been generated.^{21,22} In their retinas, we have found that *sst*₁ loss causes an increased expression and function of *sst*₂.^{23–28}

In the present study, retinas of *sst*₁- and *sst*₂-KO mice were rendered hypoxic and were used to investigate whether altered levels of *sst*₂ play a role in regulating retinal angiogenesis and its associated factors. Our hypothesis was that, compared with wild-type (WT) retinas, the lack of *sst*₂ is associated with heavier effects of hypoxia, whereas a chronic overexpression of *sst*₂ (as in *sst*₁-KO retinas) should attenuate these effects.

METHODS

Animals

Experiments were performed on 128 mice of WT (C57BL/6) and *sst*₁- or *sst*₂-KO strains of both sexes at postnatal day (PD)17 (6 g body weight). In some experiments designed to evaluate development of retinal vasculature, five PD12 mice for each strain were also used. *sst*₁- and *sst*₂-KO mice were generated as previously reported.^{21,22} Experiments were performed in agreement with the ARVO Statement for the Use of Animals in Ophthalmic and Vision Research and in compliance with the Italian law on animal care 116/1992 and EEC/609/86. All efforts were made to reduce the number of animals used.

Model of Hypoxia-Induced Retinopathy

In a typical model of hypoxia-induced retinopathy,²⁹ litters of mouse pups with their nursing mothers were exposed to a high oxygen concentration (75% ± 2%) between PD7 and PD12 in an infant incubator. Oxygen was checked twice daily with an oxygen analyzer (Miniox I; Bertocchi srl Elettromedicali, Cremona, Italy). After exposure to room air between PD12 and PD17, the mice were anesthetized by intraperitoneal injection of Avertin (1.2% tribromoethanol and 2.4% amylene hydrate in distilled water, 0.02 mL/g body weight; Sigma-Aldrich, St. Louis, MO). Mice kept in room air were used as control animals. All experiments were performed at the same time of day, to exclude possible circadian influences. The data were collected from both males and females and the results combined, as there was no apparent gender difference.

Assessment of Retinal Vascularization

Fluorescein-conjugated dextran perfusion of the retinal vessels was performed as previously described.³⁰ Briefly, animals were anesthetized, a median sternotomy was performed, and the left ventricle was perfused with 2 mL of a 25-mg/mL solution of fluorescein-conjugated dextran (Sigma-Aldrich) in 0.15 M phosphate buffer (PB). The eyes were enucleated, the retinas were dissected, and flatmounts were obtained. They were viewed by fluorescence microscopy (Eclipse E800; Nikon, Badhoevedorp, The Netherlands), and images were acquired (DFC320 camera; Leica Microsystems, Heidelberg, Germany). For the evaluation of retinopathy, we considered separately the formation of new vessels and the extent of loss of vessels in the central retina. Neovascularization was evaluated with the retinopathy scoring system shown in Table 1. Three trained observers evaluated the number of clock hours with abnormal vessels for each retina ($n = 12$ for each strain). The data were averaged and are expressed in values ranging from 0 to 8. A higher score indicates more severe retinopathy. For evaluation of the avascular area, we used a method previously described.⁷ The avascular area and the total retinal area were measured in retinal images ($n = 12$ for each strain) with computer-assisted analysis (Axiovision 4 software; Carl Zeiss Vision GmbH, München-Hallbergmoos, Germany). For measurement of the capillary-free area, blind-coded retinal flatmounts were analyzed. Data are expressed as the percentage of the avascular area in relation to the total area. A direct comparison between aberrant retinal vessels revealed by fluorescein angiography and histologic cross sections (10- μ m thick) was performed in the flatmounts used for retinopathy evaluation.

Measurements of mRNA Levels by Semiquantitative RT-PCR

RT-PCR in mouse retinas ($n = 8$ for each strain) was performed as previously described.²⁷ Briefly, anesthetized mice were killed by cervical dislocation, and the eyes were rapidly removed. After removal of the anterior segments, dissected retinas were homogenized in extraction reagent (TRIzol; Invitrogen, Carlsbad, CA). First-strand cDNA was generated from 1 μ g of total RNA, and one tenth of the RT product was amplified in a total volume of 25 μ L, using 1.25 U *Taq* polymerase. mRNAs of angiogenesis-associated growth factors and their receptors

were coamplified with S16 mRNA whereas *sst*₂ mRNA was coamplified with cyclophilin B mRNA in an automatic thermocycler (Bio-Rad, Hercules, CA). Both cyclophilin B mRNA and S16 mRNA were used as internal standards. Forward and reverse primers were chosen from mouse sequences and are listed in Table 2. A 20- μ L sample of the PCR reaction was electrophoresed on a 4% agarose gel (Eurobio, Les Ulis, France) and stained (GelStar; BMA, Rockland, ME). After migration, bands corresponding to the amplified products were analyzed (Gel Doc 2000 System equipped with Quantity One software; Bio-Rad). For semiquantitative analysis of the PCR products, we measured the signal intensity of the bands with respect to intensity of the signal for either S16 or cyclophilin B in the same lane (mRNA/S16 mRNA or mRNA/cyclophilin B mRNA).

Immunohistochemistry

Immunohistochemistry was performed in the retinas of three anesthetized mice for each strain and killed by cervical dislocation. The eyes were removed and immersion fixed in 4% paraformaldehyde in 0.1 M PB (pH 7.4) for 1 hour. The fixed eyes were transferred to 25% sucrose in 0.1 M PB and stored at 4°C. Retinal sections were cut perpendicular to the vitreal surface at 10 μ m with a cryostat, mounted on gelatin-coated slides, and stored at -20°C. Primary rabbit antisera directed to VEGF, VEGFR-1, VEGFR-2, IGF-1 (1:100 dilution), and the β subunit of IGF-1R (1:30 dilution; Santa Cruz Biotechnology, Santa Cruz, CA) were used. In double-labeling experiments, a mouse monoclonal antibody directed to glutamine synthetase (Chemicon, Temecula, CA) was also used as a Müller cell marker³⁴ at 1:500 dilution in conjunction with VEGFR-2, IGF-1, and IGF-1R antibodies. Goat anti-rabbit and anti-mouse secondary antibodies conjugated with Alexa Fluor 488 or Alexa Fluor 546 (Invitrogen-Molecular Probes, Eugene, OR) were used at a dilution of 1:200. Control experiments included the omission of the primary antibodies. Nonspecific staining was not observed. Immunofluorescence images were acquired with a 40 \times objective, a digital camera (Plan-Neofluar Zeiss Axiocam MRC; Carl Zeiss Meditec, GmbH) connected to an epifluorescence microscope, and software (Axiovision 4; Carl Zeiss Meditec, GmbH). The digital images were sized and optimized for contrast and brightness (Photoshop 5.0; Adobe Systems, Mountain View, CA). Final images were saved at a minimum of 300 dpi.

Statistical Analysis

Data were analyzed by the Kolmogorov-Smirnov test on verification of normal distribution. Statistical significance was evaluated with ANOVA followed by the Newman-Keuls multiple comparison post test (Prism; GraphPad Software, San Diego, CA). Numerical data are expressed as the mean ± SE. Differences with $P < 0.05$ were considered significant.

RESULTS

Retinal Neovascularization

In both WT and KO retinas, exposure to 75% ± 2% oxygen between PD7 and PD12 resulted in the disappearance of existing capillaries in the central retina, although the peripheral

TABLE 1. Retinopathy Scoring System

Criteria	Points				
	0	1	2	3	4
Blood vessel tufts	None	In <3 clock hours	In 3–5 clock hours	In 6–8 clock hours	In 9–12 clock hours
Blood vessel tortuosity	None	<1/3 of vessels	1/3–2/3 of vessels	>2/3 of vessels	
Retinal hemorrhage	Absent	Present			

Flat-mounted retinas were examined by fluorescence microscopy and retinopathy was quantified by evaluating three criteria. Points received for each criterion were summed to obtain the retinopathy score. A higher score (range, 0–8) indicates more severe retinopathy. The scoring system was adapted from Higgins et al.³¹

retina remained vascularized (data not shown). Recovery in room air until PD17 allowed revascularization of the central avascular portion with associated marked neovascularization at the border between the central avascular and peripheral vascularized retina. Figure 1 shows the vascular pattern of flat-mounts under normoxic (Fig. 1A-C) and hypoxic (Figs. 1D-F) conditions from WT (Figs. 1A, 1D), *sst₁*-KO (Figs. 1B, 1E), and *sst₂*-KO (Figs. 1C, 1F) mice. No differences were observed among normoxic WT and KO retinas. In both WT and KO mice returned to room air after exposure to high oxygen concentration, the central loss of blood vessels and the formation of engorged vessel tufts were observed. Evaluation of new vessel

formation demonstrated that WT and *sst₁*-KO mice did not significantly differ in their median total retinopathy score, with respective values of 4.4 ± 0.33 and of 4.1 ± 0.22 (Fig. 2A). In contrast, the retinopathy score in *sst₂*-KO retinas was significantly higher than in WT or in *sst₁*-KO mice (6.9 ± 0.17 ; $P < 0.01$). Similarly (Fig. 2B), no differences between WT and *sst₁*-KO retinas were observed with measurements of the capillary-free area ($3.7\% \pm 0.65\%$ and $4.9\% \pm 0.44\%$, respectively), whereas a significant increase by approximately 90% was found in *sst₂*-KO ($8.3\% \pm 0.15\%$; $P < 0.01$). A direct comparison between aberrant retinal vessels revealed by fluorescein angiography is shown in the high-resolution, cross-sectional

FIGURE 1. Flatmounted retinas perfused with fluorescein-dextran of PD17 WT (A, D), *sst₁*-KO (B, E), and *sst₂*-KO (C, F) mice exposed to room air (A-C) or to $75\% \pm 2\%$ oxygen (D-F) from PD7 to PD12. Hyperoxia followed by normoxia for 5 days produced the central loss of blood vessels and the formation of vessel tufts with more evident effects in *sst₂*-KO retinas (F) when compared to WT (D) and *sst₁*-KO (E) retinas. Magnification, $\times 4$.

FIGURE 2. Effects of hypoxia on retinal vascularization. **(A)** Retinopathy scores (means \pm SE) were significantly higher in *sst*₂-KO than in WT and *sst*₁-KO retinas (**P* < 0.01, ANOVA). **(B)** Capillary-free areas (means \pm SE) were significantly higher in *sst*₂-KO than in WT and *sst*₁-KO retinas (**P* < 0.01, ANOVA).

images of retinal vessels in the different strains (Fig. 3). Morphologically similar neovascular tufts extending into the vitreous were observed in all strains.

***sst*₂ mRNA**

Semiquantitative RT-PCR on mouse retina samples yielded amplified products at 76 bp (*sst*₂). Normoxic and hypoxic retinas had comparable levels of *sst*₂ mRNA. In the absence of *sst*₁, *sst*₂ mRNA was significantly higher (approximately 150%, *P* <

0.0001) than in WT retinas, in agreement with previous results,²⁷ and was not significantly different from that measured after hypoxia (Fig. 4).

VEGF, VEGFR-1, and VEGFR-2

We determined whether *sst*₂ overexpression, as in *sst*₁-KO retinas, or *sst*₂ deletion was accompanied by alterations in mRNA levels of VEGF, VEGFR-1, and VEGFR-2. RT-PCR yielded amplified products at 221-, 201-, and 198-bp, which correspond to VEGF, VEGFR-1, and VEGFR-2 mRNA, respectively (Figs. 5A-C). Normoxic mRNA levels in WT retinas did not

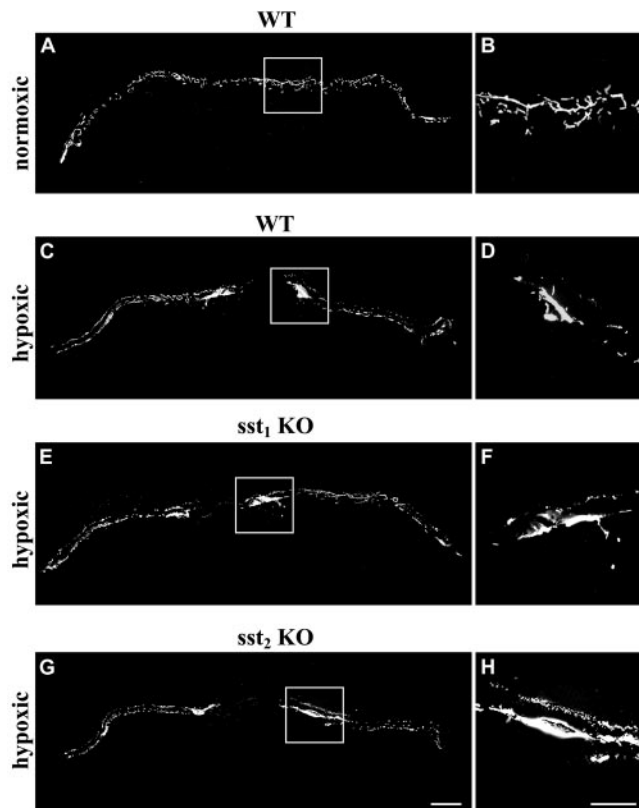

FIGURE 3. Retinal sections cut with a cryostat from the flatmount used for fluorescein angiography. These cross-sectional images show fluorescein-labeled retinal vessels in normoxic WT (A), hypoxic WT (C), hypoxic *sst*₁-KO (E) and hypoxic *sst*₂-KO (G) retinas. High-power images of the boxed areas, representing vascular tufts typical of hypoxic retinas, are in (B), (D), (F), and (H), respectively. Scale bars: (A, C, E, G) 200 μ m; (B, D, F, H) 100 μ m.

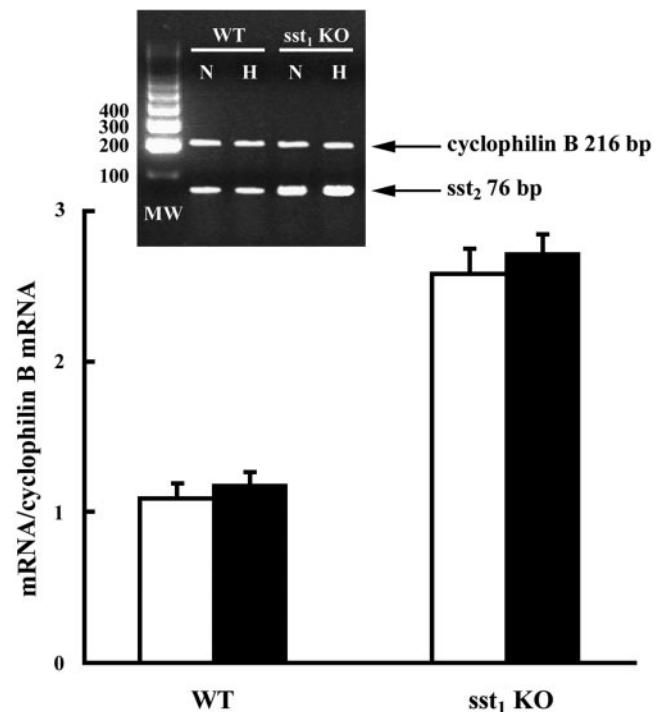

FIGURE 4. Semiquantitative RT-PCR of *sst*₂ mRNA (band at 76 bp in the inset) in both normoxic (\square ; lane N in the inset) and hypoxic (\blacksquare ; lane H in the inset) WT and *sst*₁-KO retinas. Cyclophilin B mRNA was used as internal standard (band at 216 bp in the inset). Hypoxia did not affect *sst*₂ mRNA in both WT and KO. *sst*₂ mRNA in *sst*₁-KO retinas was approximately 150% higher than in WT retinas (*P* < 0.0001; ANOVA). Each column represents the mean \pm SE of eight samples. Each sample refers to the mRNA extracted from six retinas.

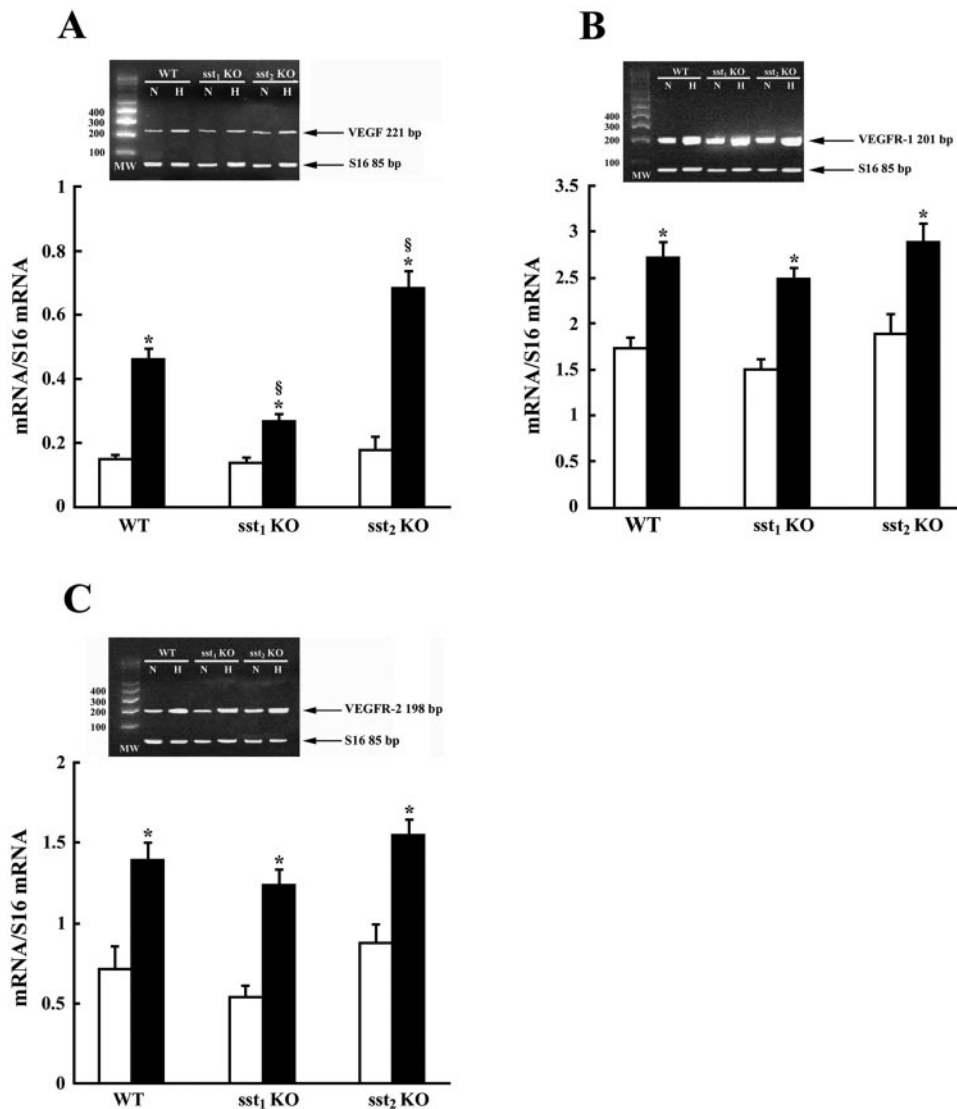

FIGURE 5. Semiquantitative RT-PCR of VEGF mRNA (band at 221 bp in the *inset* in A), VEGFR-1 mRNA (band at 201 bp in the *inset* in B) and VEGFR-2 mRNA (band at 198 bp in the *inset* in C) in both normoxic (□; lane N in the *insets*) and hypoxic (■; lane H in the *insets*) WT, sst₁-KO, and sst₂-KO retinas. S16 mRNA was used as internal standard (band at 85 bp in the *insets*). (A) Normoxic VEGF mRNA did not differ among strains, but it was significantly increased by hypoxia (* $P < 0.01$; ANOVA) to reach a value that was lower in sst₁-KO than in WT retinas (§ $P < 0.05$; ANOVA) but higher in sst₂-KO than in WT retinas (§ $P < 0.05$; ANOVA). (B, C) Normoxic levels of both VEGFR-1 mRNA and VEGFR-2 mRNA did not differ among strains but were significantly increased by hypoxia (* $P < 0.01$; ANOVA). Each column represents the mean \pm SE of eight samples. Each sample refers to the mRNA extracted from six retinas.

differ significantly from those in KO retinas. In contrast, hypoxia significantly increased ($P < 0.01$) mRNA levels of VEGF (~200%), VEGFR-1 (~55%), and VEGFR-2 (~90%) in all strains. After hypoxia (Fig. 5A), VEGF mRNA was significantly lower in sst₁-KO (~40%, $P < 0.05$) than in WT, but it was significantly higher in sst₂-KO retinas (~50%, $P < 0.05$). The relative levels of VEGF receptor messengers did not differ significantly among strains (Figs. 5B, 5C).

VEGF-immunoreactivity (IR) in normoxic retinas (Fig. 6A) was prominent in cone photoreceptors and in the outer plexiform layer (OPL). Lighter staining was in the ganglion cell layer (GCL) and in the inner nuclear layer (INL) in putative bipolar cells originating processes directed to the inner plexiform layer (IPL). Rare vessels in the inner retina displayed faint VEGF-IR. The same pattern of VEGF-IR was observed in normoxic sst₁-KO and sst₂-KO retinas (data not shown). In WT and in sst₁-KO hypoxic retinas (Figs. 6B, 6C), the overall level of VEGF-IR was consistently increased compared with WT normoxic retinas. In particular, VEGF-IR was more intense in the OPL, in the GCL and in blood vessels. In sst₂-KO hypoxic retinas (Fig. 6D), the increase of VEGF-IR intensity was more pronounced than that in WT or in sst₁-KO retinas.

VEGFR-1-IR was mainly in the OPL of normoxic retinas (Fig. 6E). Photoreceptor outer segments were also immunolabeled.

A lighter immunofluorescence was detected in numerous cell somata in the INL and the GCL. Some vessels of the inner retina were also faintly immunolabeled. The immunofluorescence intensity was evidently increased in the vessels as well as in all retinal layers after hypoxia in a similar way in WT (Fig. 6F), sst₁-KO (Fig. 6G), and sst₂-KO (Fig. 6H) retinas compared with the respective normoxic retinas.

VEGFR-2-IR was detected in numerous putative Müller cell processes and in faintly labeled cell bodies within the GCL of normoxic WT retinas (Fig. 6I). Occasional blood capillaries were also lightly labeled. The same pattern was observed in normoxic sst₁- and sst₂-KO retinas (data not shown). In both WT and KO, the immunofluorescence intensity was increased after hypoxia, particularly in the walls of retinal capillaries (Figs. 6J–L). The localization of VEGFR-2-IR to Müller cells was confirmed by the results of double-labeling experiments (Fig. 7A, 7B).

IGF-1 and IGF-1R

RT-PCR on both WT and KO mice yielded amplified products at 351- and 161-bp, which correspond to IGF-1 and IGF-1R mRNA, respectively (Fig. 8). Normoxic IGF-1 mRNA in WT retinas did not differ significantly from that in sst₁-KO retinas, but it was significantly higher than in sst₂-KO ($P < 0.001$, Fig.

FIGURE 6. Immunohistochemical patterns of VEGF (A–D), VEGFR-1 (E–H), and VEGFR-2 (I–L). In normoxic retinas, there were no apparent differences in the immunohistochemical patterns of WT, *sst*₁-KO, and *sst*₂-KO retinas. (A) Normoxic, VEGF immunostained WT retina. VEGF immunostaining was in the cone photoreceptors, the outer plexiform layer (OPL), putative bipolar cells (arrow), and the ganglion cell layer (GCL). (B) Hypoxic WT retina. The overall VEGF immunofluorescence intensity was higher than in the normoxic retina. VEGF immunostaining became clearly visible in several retinal capillaries (arrowheads). (C, D) Hypoxic *sst*₁-KO and *sst*₂-KO retinas, respectively. The increase in immunofluorescence intensity was particularly evident in the OPL and in the GCL of the *sst*₂-KO retinas (D). (E) Normoxic, VEGFR-1-immunostained WT retina. VEGFR-1 immunostaining was mainly in the OPL and in lightly stained blood vessels (arrow). In hypoxic WT (F), *sst*₁-KO (G), and *sst*₂-KO (H) retinas, the VEGFR-1 immunostaining became evident in the inner nuclear layer (INL) and GCL and in the walls of retinal capillaries (F, G, arrowheads). (I) Normoxic, VEGFR-2-immunostained WT retina. VEGFR-2 immunostaining was mainly in vertically directed processes probably belonging to Müller glial cells and in faintly stained cells in the GCL. In hypoxic WT (J), *sst*₁-KO (K) and *sst*₂-KO (L) retinas, the VEGFR-2 immunofluorescence intensity increased. In particular, blood vessels became highly immunostained (J–L, arrows). Scale bar, 20 μ m.

8A). In both WT and *sst*₁-KO, hypoxia did not affect IGF-1 mRNA which was, in contrast, increased by approximately threefold in *sst*₂-KO retinas ($P < 0.001$), reaching a level similar to that in WT and *sst*₁-KO. In both WT and KO retinas, hypoxia significantly increased IGF-1R mRNA ($P < 0.01$). IGF-1R mRNA was significantly lower in *sst*₁-KO (~40%, $P < 0.05$) than in WT retinas after hypoxia, whereas IGF-1R mRNA was significantly higher in *sst*₂-KO (~40%, $P < 0.05$) than in WT (Fig. 8B).

As depicted in Figures 9A–D, IGF-1-IR was detected in all retinal layers, and it was prominent in the OPL and in GCL somata. In the outer nuclear layer (ONL), it was detected in Müller cell processes, as confirmed by double-labeling experiments (Figs. 7C, 7D). In normoxic retinas, the IGF-1 staining in the WT (Fig. 9A, left) was similar to that in *sst*₁-KO retinas (data not shown). In contrast, the immunofluorescence intensity

was drastically reduced in *sst*₂-KO retinas, where it appeared unchanged in the OPL, but it was markedly reduced in all other retinal layers (Fig. 9A, right). In hypoxic retinas of all strains, the immunostaining pattern was similar to that in normoxic WT retinas (Figs. 9B–D).

In normoxic retinas (Fig. 9E), IGF-1-IR was prominent in the OPL and sparse throughout the IPL. The outline of several somata in the mid-distal INL showed light immunostaining. In addition, IGF-1-expressing Müller cells were also detected as confirmed by double-labeling experiments (Figs. 7E, 7F). Retinal capillaries did not display IGF-1-IR. The same pattern was observed in normoxic *sst*₁-KO and *sst*₂-KO retinas (data not shown). In hypoxic retinas of WT, *sst*₁-KO, and *sst*₂-KO mice, the IGF-1-IR immunofluorescence intensity was dramatically increased in all retinal layers, particularly in the IPL and in Müller cell processes (Figs. 9F–H).

(B) The same field as in (A) showing glutamine synthetase immunolabeling. (C) IGF-1 immunostaining. (D) The same field as in (C) showing glutamine synthetase immunolabeling. (E) IGF-1R immunostaining. (F) The same field as in (E) showing glutamine synthetase immunolabeling. Arrows: double-labeled Müller cell processes. INL, inner nuclear layer; ONL, outer nuclear layer; OPL, outer plexiform layer. Scale bar, 10 μ m.

Ang/Tie mRNA

RT-PCR yielded amplified products at 278-, 375-, 363- and 253-bp, which correspond to Ang-1, Ang-2, Tie-1, and Tie-2 mRNA, re-

spectively (Figs. 10A–D). Normoxic mRNA levels in WT retinas did not differ significantly from those in KO retinas except for Ang-2 mRNA, which was significantly higher (~15%) in *sst*₂-KO than in WT ($P < 0.0001$), and Tie-2 mRNA, which was significantly higher (~40%) in both *sst*₁- and *sst*₂-KO than in WT ($P < 0.0001$) retinas. Hypoxia did not affect Ang-1 mRNA in either WT or *sst*₁-KO retinas, whereas it significantly decreased Ang-1 mRNA (~20%) in *sst*₂-KO ($P < 0.01$). In contrast, hypoxia significantly increased ($P < 0.00001$) mRNA levels of Ang-2 (~20%) in both WT and *sst*₁-KO retinas, but not in *sst*₂-KO. Tie-1 mRNA was not influenced by hypoxia in WT, whereas it was either increased (~20%, $P < 0.001$) in *sst*₁-KO or decreased (~45%, $P < 0.00001$) in *sst*₂ KO. After hypoxia, Tie-2 mRNA increased significantly in WT (~15%, $P < 0.01$), remained unchanged in *sst*₁-KO and decreased significantly in *sst*₂-KO (~30%, $P < 0.00001$) retinas.

DISCUSSION

In this study, we report findings regarding the function of *sst*₂ in the control of angiogenesis and its associated factors in a model of hypoxia-induced retinal neovascularization in transgenic mice with altered *sst*₂ levels in the retina.^{23,25,27} Our hypothesis that modulation of *sst*₂ may provide an effective mechanism for regulation of retinal neovascularization has been satisfied, at least in part. Indeed, although a chronic overexpression of *sst*₂ (as in *sst*₁-KO retinas) did not attenuate retinal neovascularization, the lack of *sst*₂ was associated with significantly worsened neovascularization. We also show that *sst*₂ levels in the retina differentially influenced angiogenesis-associated factors, thus indicating a strain-dependent expression of these factors that may determine heterogeneity in the angiogenic response and, potentially, susceptibility to angiogenesis-dependent diseases.

Effects of Hypoxia on Angiogenesis-Associated Growth Factors

As shown by our results in WT mice, both the expression of VEGF and its receptors and that of the proangiogenic factor Ang-2 and its receptor Tie-2, increased as a result of hypoxia, in agreement with previous observations.^{7,11,12,35,36} The fact that hypoxia did not influence Ang-1 is in line with previous results in human retinas with ischemia-induced neovascularization,³⁷ although a slight increase in Ang-1 expression has been re-

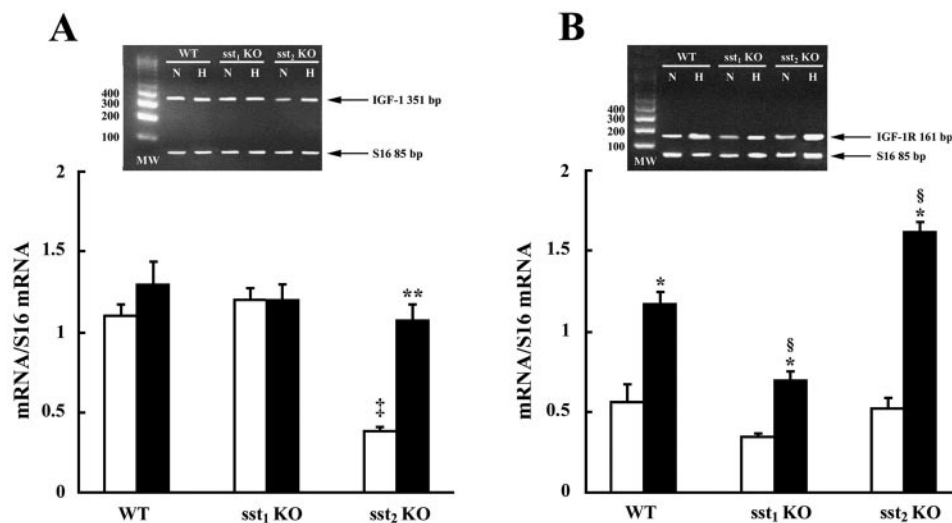

FIGURE 8. Semiquantitative RT-PCR of IGF-1 mRNA (band at 351 bp in the inset in A) and IGF-1R mRNA (band at 161 bp in the inset in B) in both normoxic (□; lane N in the insets) and hypoxic (■; lane H in the insets) WT, *sst*₁-KO, and *sst*₂-KO retinas. S16 mRNA was used as the internal standard (band at 85 bp in the insets). (A) Normoxic levels of IGF-1 mRNA were similar in WT and *sst*₁-KO whereas IGF-1 mRNA in *sst*₂-KO retinas was significantly lower than in WT and *sst*₁-KO ($\ddagger P < 0.001$; ANOVA). Hypoxia did not affect IGF-1 mRNA in both WT and *sst*₁-KO retinas, whereas IGF-1 mRNA in *sst*₂-KO retinas was significantly higher than in normoxia ($**P < 0.001$; ANOVA). (B) Normoxic levels of IGF-1R mRNA did not differ among strains. They were significantly increased by hypoxia ($*P < 0.01$;

ANOVA), reaching a level that was significantly lower in *sst*₁-KO than in WT ($\S P < 0.05$; ANOVA), but significantly higher in *sst*₂-KO than in WT retinas ($\S P < 0.05$; ANOVA). Each column represents the mean \pm SE of eight samples. Each sample refers to the mRNA extracted from six retinas.

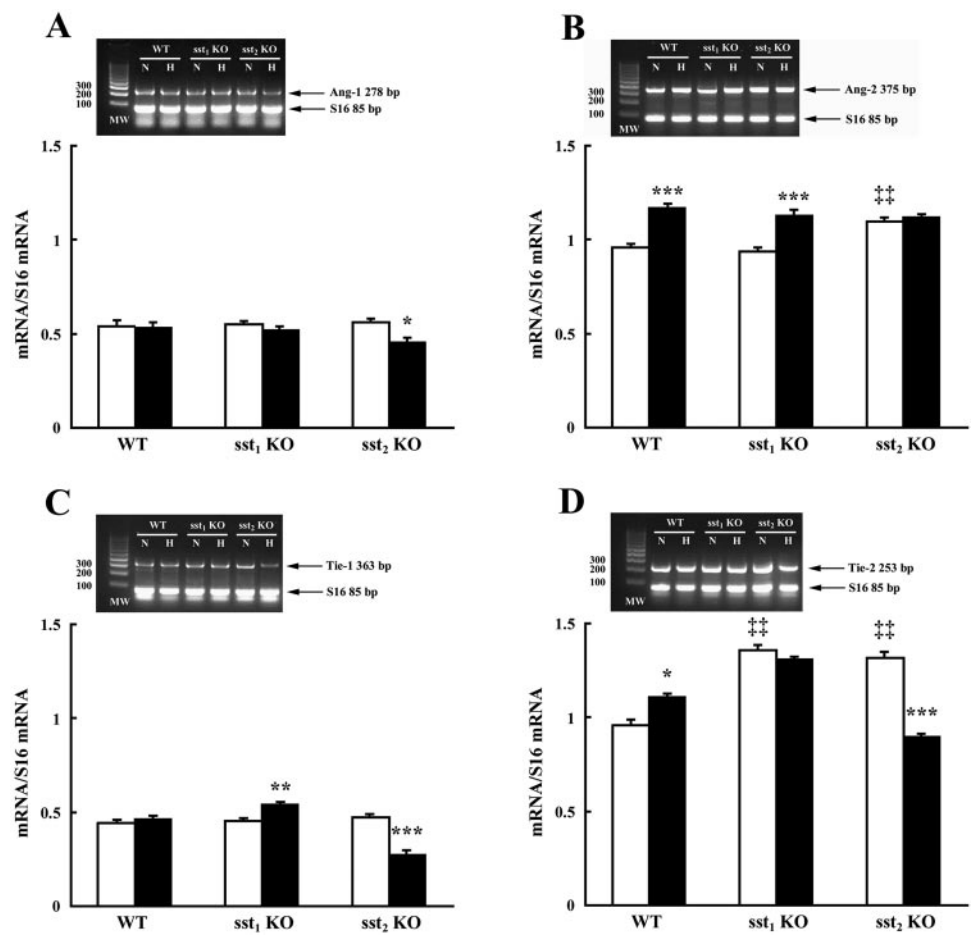

FIGURE 9. Immunohistochemical patterns of IGF-1 (A–D) and IGF-1R (E–H). (A) Normoxic, IGF-1-immunostained WT retina (left) and normoxic, IGF-1-immunostained *sst*₂-KO retina (right). IGF-1-IR was evident in the outer plexiform layer (OPL) and in the ganglion cell layer (GCL). IGF-1-IR was also in putative Müller cell processes in the outer nuclear layer (ONL). The immunofluorescence intensity was drastically reduced in the *sst*₂-KO retina. In hypoxic WT (B), *sst*₁-KO (C) and *sst*₂-KO (D) retinas, the IGF-1 immunostaining pattern was similar to that in normoxic WT retinas. (E) Normoxic, IGF-1R-immunostained WT retina. IGF-1R immunostaining was prominent in the OPL and faint in the inner plexiform layer (IPL). Cells in the distal inner nuclear layer (INL) and putative Müller cell processes were also labeled. In hypoxic WT (F), *sst*₁-KO (G) and *sst*₂-KO (H) retinas, the IGF-1R immunofluorescence intensity was increased in all retinal layers. Scale bar, 20 μ m.

ported in hypoxic mouse retinas.¹¹ Our results also demonstrate that retinal IGF-1 mRNA did not change after hypoxia, whereas the expression of IGF-1R significantly increased, in

agreement with previous results demonstrating increased levels of retinal IGF-1R mRNA, but not of IGF-1 mRNA, in hypoxic rat retinas.³⁸ That neovascularization is not associated with

FIGURE 10. Semiquantitative RT-PCR of Ang-1 mRNA (band at 278 bp in the inset in A), Ang-2 mRNA (band at 375 bp in the inset in B), Tie-1 mRNA (band at 363 bp in the inset in C), and Tie-2 mRNA (band at 253 bp in the inset in D) in both normoxic (□; lane N in the insets) and hypoxic (■; lane H in the insets) WT, *sst*₁-KO, and *sst*₂-KO retinas. S16 mRNA was used as internal standard (band at 85 bp in the insets). (A) Ang-1 mRNA was not affected by hypoxia except for showing a significant decrease in *sst*₂-KO retinas ($^{*}P < 0.01$; ANOVA). (B) Ang-2 mRNA was significantly increased by hypoxia in both WT and *sst*₁-KO ($^{***}P < 0.00001$; ANOVA). Normoxic level of Ang-2 mRNA in *sst*₂-KO retinas was significantly higher than in WT and *sst*₁-KO ($^{*}P < 0.0001$; ANOVA) and comparable to that measured after hypoxia. (C) Hypoxia significantly increased Tie-1 mRNA in *sst*₁-KO ($^{**}P < 0.001$; ANOVA) whereas significantly decreased Tie-1 mRNA in *sst*₂-KO ($^{***}P < 0.00001$; ANOVA). (D) Normoxic levels of Tie-2 mRNA in KO were significantly higher than in WT ($^{*}P < 0.0001$; ANOVA). Hypoxia significantly increased the level of Tie-2 mRNA in WT ($^{*}P < 0.01$; ANOVA), did not affect Tie-2 mRNA in *sst*₁-KO, whereas it significantly decreased Tie-2 mRNA in *sst*₂-KO ($^{***}P < 0.00001$; ANOVA). Each column represents the mean \pm SE of eight samples. Each sample refers to the mRNA extracted from six retinas.

altered IGF-1 mRNA has also been recently demonstrated in different models of retinopathy in mice.^{8,9}

Influence of sst₂ Levels on Angiogenesis-Associated Growth Factors

Our results demonstrate that enhanced somatostatinergic function at sst₂ limited the hypoxia-induced VEGF increase, whereas sst₂ loss upregulated this increase. Thus, sst₁-KO retinas were protected to some extent from hypoxia which, in contrast, had a more serious influence after sst₂ loss. An SRIF-induced regulation of VEGF has been suggested,^{16,18} although there are also studies demonstrating that SRIF does not influence VEGF levels, as it does GH or IGF-1.³⁹ Our additional finding that sst₂ loss upregulated the hypoxia-induced increase of IGF-1R mRNA suggests the possibility that sst₂ may regulate VEGF expression through an increased expression of IGF-1R. In this respect, results from human RPE cells demonstrate that activation of sst₂ inhibits IGF-1R phosphorylation and the downstream VEGF synthesis.¹⁶ Our finding that normoxic levels of IGF-1 mRNA were drastically decreased by sst₂ loss is difficult to explain, since activation of sst₂ is known to decrease IGF-1.¹⁷ One possibility is that sst₂ loss causes excessive stimulation of IGF-1R which would in turn elicit feedback mechanisms to decrease IGF-1 expression. These mechanisms would be removed in hypoxia, as we observed that, in the absence of sst₂, IGF-1 mRNA expression was enhanced, and it reached levels that were comparable to those in WT or in sst₁-KO retinas. As also shown by our results, sst₂ levels appeared to influence the effects of hypoxia on the Ang/Tie system. Ang-1, acting on Tie-2, is known to promote vascular integrity and maturation, whereas Ang-2 is an antagonist of Ang-1 and promotes VEGF-induced proliferation of endothelial cells.⁴⁰ In addition, Tie-1 promotes structural integrity of endothelial cells.⁴¹ We found that, after hypoxia, Ang-1, Tie-1, and Tie-2 mRNAs were decreased in the absence of sst₂, whereas Tie-1 mRNA was increased when sst₂ was overexpressed, as in sst₁-KO retinas. Together, these results add further evidence to the possibility that sst₂ may be beneficial in limiting hypoxia-induced neovascularization in the retina.

Immunohistochemical Observations

Our immunohistochemical observations are consistent with the data of mRNA expression as evaluated with RT-PCR. Of interest, in WT as well as in KO retinas, the hypoxia-induced increase of VEGFR-1 and -2 mRNA is paralleled by a pronounced increase of VEGFR-1 and -2 immunolabel intensity in retinal vessels, consistent with a direct action exerted by VEGF on retinal vessels in hypoxic conditions.³⁶ In addition, the hypoxia-induced increase in VEGF immunofluorescence intensity is more pronounced in sst₂-KO than in WT or in sst₁-KO retinas, thus implementing our data on effects of sst₂ loss on retinal neovascularization.

Although localization of VEGF, IGF-1 and their receptors to retinal cells is still controversial, and different retinal patterns of immunohistochemical or in situ hybridization labeling have been reported in different species,^{2-6,42-44} our immunohistochemical results demonstrate that these molecules are predominantly expressed by neuronal elements and glial cells and only to a minor extent by retinal vessels. In particular, VEGFR-2, IGF-1, and IGF-1R have been localized to Müller cells in agreement with previous results.⁴⁵ Our observation of IGF-1 localization to Müller cells is in agreement with reports of these cells as an important source of retinal IGF-1.^{6,46} In addition, a substantial body of information suggests that Müller cells are involved in proliferative diabetic retinopathy.⁴⁷ Finally, the localization of angiogenesis-associated factors to retinal neural

and glial elements is in agreement with proposed functions of these factors that may be related to neuronal survival.⁴⁸⁻⁵⁰

CONCLUSION

The present study demonstrates that sst₂ exerts protective effects against retinal neovascularization and suggests that sst₂ agonists are useful in retinal diseases characterized by neovascularization. The immediate clinical importance lies in the establishment of a potential pharmacologic target based on sst₂ pharmacology.
